

Intergenerational Housing Misallocation and Fertility

Short model note

Tommaso De Santo

June 2026

I set up a simplified version of the model. There are two types of agents, young and old, children require space, and a combination of a down payment friction and a tax friction generates intergenerational misallocation which impacts fertility. Results are preliminary, and proofs are omitted. The model draws inspiration from [Coven et al. \(2025\)](#). In this simplified version, fertility is continuous.

1 Environment

The economy is populated by overlapping generations of young and old households. A young household has type $i = (y_i, a_i)$: income and wealth at entry. Wealth is inherited from the previous old generation¹. A household decides whether to enter the economy; inside, she chooses a tenure (rent or own), a house size, completed fertility, and savings for old age. Old households, indexed by j , are of two kinds. Old incumbents, last period's young owners, who enter old age with financial wealth, the house they bought, and a possible accrued gain, choose how much of the house to keep and how large an estate to leave, then exit. The other type is old renters, last period's young renter entrants, who rent in old age and carry no wedge. Nonentrants stay outside the market in both periods. Each period a mass $\bar{M}$ of potential young households enters the pool: the maturing children of the previous cohort plus a renewal inflow. Types are distributed according to an exogenous G_Y .

Preferences. Households have preferences over consumption, housing, and children. Children raise the household's consumption and housing needs: each child claims $\chi > 0$ units of consumption and $\kappa > 0$ units of space, so with consumption spending c_i , housing h_i , and fertility n_i ,

$$u_i^Y = \log(c_i - \chi n_i) + \alpha \log(h_i - \kappa n_i) + \vartheta \log n_i.$$

Old households value consumption, housing, and the bequest $e_j \geq 0$ they leave at exit:

$$u^O = \log c_j^O + \gamma \log h_j^O + \mathcal{B}(e_j),$$

with $\mathcal{B}$ a warm-glow function, increasing and concave, possibly zero, common to all old households. The exiting cohort's estates are what the arriving cohort inherits.

Housing. There is a fixed stock $\bar{H}$ of divisible floorspace, held by old incumbents and by passive absentee landlords: buyers purchase from either, renters occupy landlord space, and rents and sale

¹Distributed randomly, without a tie to bequests and inheritants. It can be distributed unequally, however.

proceeds are transfers.² Renting and owning are occupancy modes with different size limits, the largest sizes available to rent and to own,

$$h \leq \bar{h}^R \text{ (rent)}, \quad h \leq \bar{h}^O \text{ (own)}, \quad \bar{h}^R < \bar{h}^O,$$

Family-sized houses are mostly available to buy, not to rent. All floorspace trades in one market: the asset price is P , and no-arbitrage ties the rental rate to it,

$$q = \rho P, \quad \rho = r + \delta + \tau^P.$$

The renter pays q as rent; the owner pays it as mortgage interest, property tax, depreciation, and the forgone return on her equity—different payments, equal per-unit value by arbitrage. Given q , a higher property tax lowers P and with it the down payment on any given house.

Financing. A buyer finances at most a share $\phi \in (0, 1)$ of the purchase, so she posts a down payment $(1 - \phi)Ph$ at purchase, out of her liquid wealth. Households can save in an exogenously provided bond, but renters cannot borrow. The interest rate r is exogenous.

Taxes. Two taxes appear: the property tax τ^P , part of the user cost above, and the capital-gains tax. Selling a house triggers a tax: the seller pays the rate τ^g on the difference between the sale price and what she paid, in dollars. Dying instead passes the house with a stepped-up basis - the heir's purchase price is reset to the current value -so the gain is never taxed³.

Where do gains come from when the real price never moves? From inflation. Dollar prices and incomes all grow at rate ϖ , so relative prices and real choices are unaffected; but the tax form compares dollars from different dates, and a house bought one period ago shows a paper gain even though its real value is unchanged. The tax on that paper gain is real,

$$\bar{\ell} = \tau^g \frac{P \varpi}{1 + \varpi}$$

per unit sold, and this is the model's only contact with inflation. Every cohort carries the same gain, so every incumbent's unit bears $\bar{\ell}$ if sold while alive.⁴ An estate tax, by contrast, would fall on the transfer in any form and leave the sell-or-keep margin undistorted; the gains tax distorts it precisely because death forgives it. Everything is deterministic: a buyer knows the tax her future self will face⁵.

2 Households

Conditional on entry, household i chooses a tenure mode $m \in \{R, O\}$, housing, fertility, consumption and savings; old age is discounted at β . For $m \in \{R, O\}$,

$$W_i^m = \max_{c_i, h_i, n_i, a'_i} \log(c_i - \chi n_i) + \alpha \log(h_i - \kappa n_i) + \vartheta \log n_i \\ + \beta [\mathbf{1}\{m = R\} V^R(a_{j'}) + \mathbf{1}\{m = O\} V^O(a_{j'}, h_i)]$$

²There is no construction: the model allocates a fixed stock. This goes together with the stationary equilibrium focus. More sophisticated supply will follow in the extended model and the quantitative application.

³This was the essence of the point suggested by Simon. I will go a bit deeper into it in the next weeks, but it is one of the two key margins (the other being financial constraints). The idea is then: agents have an incentive to hold on to the house, because this way neither they nor their heirs pay taxes.

⁴The statutory exclusion, which exempts gains below a dollar threshold, is an institutional detail I suppress; with it, small holdings escape the tax and lock-in sorts by size.

⁵So I am resorting to a trick here to have a capital gain in a stationary model. Coven et al. (2025) have a real growth term there, but they don't have my problem with fertility. More thought is required on this.

subject to

$$c_i + qh_i + a'_i = y_i + a_i, \quad h_i \leq \bar{h}^m, \quad a'_i \geq 0, \\ \mathbf{1}\{m = O\} (1 - \phi)Ph_i \leq a_i.$$

Financial wealth carried into old age is $a_{j'} = (1 + r)a'_i - \mathbf{1}\{m = O\}qh_i$. Children have a market price: each child claims χ goods and κ units of space, and space rents at q , so providing for a child costs $\chi + \kappa q$ per period. A useful benchmark is equal scaling, $\chi = \kappa q/\alpha$: the child splits her cost between space and goods in the proportion $\kappa q/\chi = \alpha$, the same proportion in which her parents split their own spending.

The old incumbent enters with financial wealth a_j , housing H_j^0 , and an accrued gain; old households have no income. She faces a choice with respect to her housing: sell now and pay the tax, or keep it until death, when the tax is forgiven.⁶ She solves

$$V^O(a_j, H_j^0) = \max_{c_j^O, h_j^O, e_j} u^O(c_j^O, h_j^O, e_j) \\ \text{subject to } c_j^O + e_j + qh_j^O = a_j + qH_j^0 - \bar{\ell}(H_j^0 - h_j^O), \quad 0 \leq h_j^O \leq H_j^0.$$

Selling a unit nets $q - \bar{\ell}$; hence the stepped-up basis acts as a subsidy to locking in. An old renter has no carried housing and no tax:

$$V^R(a_j) = \max_{c_j^O, h_j^O, e_j} u^O(c_j^O, h_j^O, e_j) \quad \text{subject to } c_j^O + e_j + qh_j^O = a_j, \quad 0 < h_j^O \leq \bar{h}^R,$$

and at an interior choice her marginal value of space is exactly q .

Using $P = q/\rho$, owner housing is bounded by

$$H_i^O = \min \left\{ \bar{h}^O, \frac{a_i \rho}{(1 - \phi)q} \right\}, \quad H_i^R = \bar{h}^R.$$

H_i^m is the effective family-housing cap: a renter is capped by the stock, a buyer by the size limit or by collateral, whichever is shorter. Tenure is $W_i^Y = \max\{W_i^R, W_i^O\}$. Entry compares the inside value with an outside option $\bar{W}^E$ under extreme-value shocks of scale κ_E :

$$\pi_i^E = \frac{\exp\{W_i^Y/\kappa_E\}}{\exp\{W_i^Y/\kappa_E\} + \exp\{\bar{W}^E/\kappa_E\}}$$

is the probability that household i enters.

3 Equilibrium

Aggregate demand adds young households, old incumbents, and old renters, and the single market clears:

$$\bar{M} \int \pi_i^E h_i dG_Y(i) + \int h_j^O dF_O(j) + \int h_j^O dF_R(j) = \bar{H},$$

where F_O and F_R are the measures of old incumbents and old renters. A stationary equilibrium consists of a user cost q (and $P = q/\rho$), young policies and entry probabilities, old policies, and stationary objects $(\bar{M}, G_Y, F_O, F_R)$ such that:

⁶In the more realistic model we will have indivisible housing, so this will look different. With an indivisible house the choice is all-or-nothing: a strict keeper escapes the bill entirely, lock-in concentrates into a notch at the downsizing margin, and pre-saving becomes plan-contingent.

1. the policies solve the household problems above at q ;
2. the floorspace market clears, as displayed;
3. the population reproduces itself: young owners become the old incumbents, young renters the old renters, and births plus the renewal inflow recreate the cohort;
4. fiscal and financial accounts close with lump-sum transfers.

Nothing in the clearing condition asks whether the marginal family-sized unit is held by the household that values it most; that is the next section's question.

4 Equilibrium policies

The Lagrangian for a young agent is

$$\begin{aligned}\mathcal{L} = & u_i^Y + \beta V_{j'} + \lambda_i (y_i + a_i - c_i - q h_i - a'_i) \\ & + \mu_i (a_i - (1 - \phi) P h_i) + \theta_i (\bar{h}^m - h_i) + \xi_i a'_i,\end{aligned}$$

with $\mu_i = 0$ in the rental mode and $\xi_i \geq 0$ the multiplier on the no-borrowing bound $a'_i \geq 0$ for a renter.

The first-order condition for saving sets the marginal value of resources today against the return tomorrow:

$$\frac{1}{c_i - \chi n_i} = \beta(1 + r) \frac{1}{c_{j'}^O} + \xi_i, \quad \xi_i a'_i = 0,$$

which for savers ($\xi_i = 0$), under logarithmic old utility (warm glow $b \log e$ included) and interior old choices, collapses to a savings rule:

$$a'_i = \beta(1 + \gamma + b)(c_i - \chi n_i) + \mathbf{1}\{m = O\} \frac{\bar{\ell} h_i}{1 + r},$$

with γ the old housing weight and b the warm-glow weight: the household saves old age's claim on adult consumption- $k \equiv \beta(1 + \gamma + b)$ -plus her discounted future tax bill, so anticipating the lock-in tax is itself a savings motive. By the same conversion, a buyer pays an effective price $q^O = q + \bar{\ell}/(1 + r)$ per unit of space—the market price plus her own discounted lock-in tax, pre-funded through savings rather than paid as a flow—while a renter pays q ; write q^m for the mode's effective price. A unit of adult consumption commits $1 + k$ units of resources, one spent now and k carried.

Then, with no binding constraints, with lifetime resources $w_i = y_i + a_i$,

$$c_i - \chi n_i = \frac{w_i}{1 + \alpha + \vartheta + k}, \quad n_i = \frac{\vartheta w_i}{(1 + \alpha + \vartheta + k)(\chi + \kappa q^m)}, \quad h_i = \frac{\alpha w_i}{(1 + \alpha + \vartheta + k) q^m} + \kappa n_i,$$

and savings follow the rule. When the cap binds, $h_i = H_i^m$, fertility solves the condition displayed in the last section, and the budget gives the rest.

Dividing the housing derivative of $\mathcal{L}$ by the consumption derivative, $\lambda_i = 1/(c_i - \chi n_i)$, prices every multiplier in goods. For a renter this gives

$$\frac{\alpha (c_i^R - \chi n_i^R)}{h_i^R - \kappa n_i^R} = q + \zeta_i^R, \quad \zeta_i^R = \frac{\theta_i}{\lambda_i} \geq 0 :$$

the left side is u_h/u_c , her marginal rate of substitution between space and consumption—the goods she would give up for one more unit of space, holding utility fixed—and it exceeds the rent exactly by the bite of the rental size limit, computable from her observed bundle. For a young owner the same two derivatives give

$$\frac{\alpha(c_i^O - \chi n_i^O)}{h_i^O - \kappa n_i^O} = q^O + \zeta_i^O, \quad \zeta_i^O = \underbrace{\frac{\mu_i}{\lambda_i}(1 - \phi)P}_{\zeta_i^{O,F}, \text{ down payment}} + \underbrace{\frac{\theta_i}{\lambda_i}}_{\text{size limit}} :$$

her marginal value of space exceeds her effective price by the bite of whichever access constraints bind—the down payment (μ_i) or the owner size limit (θ_i). When the size limit is slack, the bundle identifies the financing bite alone (F for financing): $\zeta_i^{O,F}$ is the observed ratio minus q^O . For an old incumbent at an interior retention choice,

$$\frac{\gamma c_j^O}{h_j^O} = q - \bar{\ell} :$$

she keeps marginal space she values below what the market would pay, because selling it would realize the taxable gain. Old renters carry no such wedge: their marginal value is q .

The solved policies give the level of fertility; the first-order condition behind them shows where housing enters it. Dividing that condition by the marginal utility of consumption prices the marginal child in goods: in either tenure,

$$\underbrace{\frac{\vartheta(c_i^m - \chi n_i^m)}{n_i^m}}_{\text{willingness to pay for a marginal child}} = \underbrace{\chi + \kappa(q^m + \zeta_i^m)}_{\text{full price of a child}}.$$

A child's space requirement is priced at the household's own shadow value of space, so a binding access constraint acts as a tax of $\kappa \zeta_i^m$ per child. Children get more expensive exactly where family-sized space is hard to reach, with market prices unchanged.

5 Efficiency

This section is very preliminary, and serves as an illustration of what one can do with the wedges. The planner faces the economy's real constraints and nothing else: the stock, the size limits, goods feasibility, and the domain conditions. It does not face household budgets, since allocations are supported by lump-sum transfers, and it does not face the financing inequalities, which restrict market purchases rather than occupancy.

Proposition 1. *Hold the stationary cross-section, entry, tenure assignments, and savings fixed; the variation below resizes two owner-occupied houses and converts no tenures. The planner's surplus from moving one unit of space from an old incumbent at an interior retention choice to a young owner whose owner size limit is slack and whose financing constraint binds ($\zeta_i^{O,F} > 0$) is*

$$\underbrace{(q^O + \zeta_i^{O,F})}_{\text{buyer's marginal value}} - \underbrace{(q - \bar{\ell})}_{\text{incumbent's marginal value}} = \zeta_i^{O,F} + \frac{\bar{\ell}}{1 + r} + \bar{\ell} > 0.$$

Every term is nonnegative and the first is positive, so one such pair is enough: the competitive allocation does not solve the planner's conditional problem. Conversely, if all financing gaps and levies are zero, the allocation satisfies the planner's conditional first-order conditions.

The buyer's marginal value is her effective price plus her gap: what she would pay for one more unit. The incumbent's is the net-of-tax sale price: what releasing one more unit nets her. In the difference the market price cancels, and the two tax terms that remain are transfers the planner recovers, not resource costs. If the move must be implemented through costly financing instruments rather than direct reassignment, their marginal real cost subtracts from this surplus; if the down-payment constraint is a primitive nothing relaxes, the gap is not recoverable. The long version carries this implementation cost explicitly.

The two margins in one picture. Figure 1 draws a solved stationary case as theory. On the left, the buyer's marginal value of space falls along her constrained path and sits above her effective price by the financing gap $\zeta^{O,F}$ at her cap, while the incumbent's sits below the market price by her tax $\bar{\ell}$. Pay the incumbent for one unit at her value, $q - \bar{\ell}$; charge the buyer at hers, $q^O + \zeta^{O,F}$: both are exactly as well off as before, and $\zeta^{O,F} + \bar{\ell}/(1+r) + \bar{\ell}$ in goods is left over. On the right, completed fertility rises with the cap at rate dn/dH until the cap stops binding at h^u .

Figure 1: Misallocation and the fertility margin. Left: the collateral-capped buyer values marginal space at $q^O + \zeta^{O,F}$, above the market price; the locked-in incumbent values it at $q - \bar{\ell}$, below; the distance between the two points is the recoverable surplus. Right: completed fertility against the effective family-housing cap, with slope dn/dH at the equilibrium cap; the cap stops binding at h^u .

6 Fertility and policy

Fix a tenure mode, let H be the effective cap, write $w = y + a$ for lifetime resources, and let q^m be the mode's effective price. Concentrating the savings rule into the budget, a binding cap makes fertility solve $\vartheta/n = (1+k)\chi/(w - q^m H - \chi n) + \alpha\kappa/(H - \kappa n)$, and

$$\frac{dn}{dH} = \frac{\frac{\alpha\kappa}{(H - \kappa n)^2} - \frac{(1+k)\chi q^m}{(w - q^m H - \chi n)^2}}{\frac{\vartheta}{n^2} + \frac{(1+k)\chi^2}{(w - q^m H - \chi n)^2} + \frac{\alpha\kappa^2}{(H - \kappa n)^2}},$$

which is positive for every binding cap if and only if $\chi \leq (1 + k) \kappa q^m / \alpha$: relaxing access raises fertility whenever the child's consumption requirement does not exceed its space requirement priced at the lifetime cost of adult consumption. The savings margin loosens the condition because forced housing spending now crowds out saving alongside consumption.

Now imagine a policy that relaxes the cap. The cap has concrete components, so the policy does too: a down-payment grant raises the collateral component $a_i \rho / ((1 - \phi)q)$ of the owner cap, looser financing raises it through ϕ , and allowing larger rental units—converted from the existing stock, not built—raises $\bar{h}^R$. None of these adds floorspace: the stock is fixed, so the policy widens access to existing space rather than increasing supply. Then, at fixed prices, a small policy z moves aggregate fertility through the constrained:

$$\left. \frac{dN}{dz} \right|_q = \bar{M} \sum_m \int_{\mathcal{E}_m(z)} \left[\pi_i^E \Psi_i^m + n_i^m \frac{\pi_i^E (1 - \pi_i^E)}{\kappa_E} \Theta_i^m \right] \mathcal{P}_i^m(z) dG_Y(i),$$

where $\mathcal{E}_m(z)$ is the set of households whose cap binds in mode m , $\mathcal{P}_i^m = \partial H_i^m / \partial z$ is the pass-through of the policy to the binding component of the cap, $\Psi_i^m = dn/dH$ is the fertility response, and $\Theta_i^m = \zeta_i^m / (c_i^m - \chi n_i^m)$ drives the entry term. A policy aimed at a slack constraint moves nothing: a down-payment grant does nothing for a household pinned by the rental size limit. A transfer of spendable resources also moves fertility through the budget at a fixed cap; the formula isolates the access channel. At $\chi = (1 + k) \kappa q^m / \alpha$, equal scaling at lifetime prices, Ψ_i^m is proportional to $\zeta_i^m / (c_i^m - \chi n_i^m)$, so the same gap that measures misallocation predicts whose fertility responds.

Because tenure is a discrete choice, a policy that shifts $W_i^O - W_i^R$ also moves households across the rent-own boundary. The gains tax makes that crossing non-trivial—owning is the dear way to occupy space per unit, yet carries a constant old-age subsidy from retention—and I defer its full treatment to the long version, together with the stationary demographic closure and the full equilibrium definition.
