

Fertility and Housing Tenure Choice

Tommaso De Santo

September 14, 2026

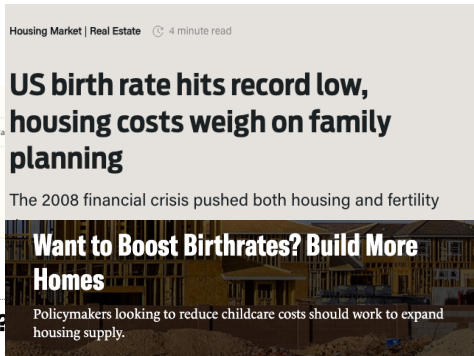

Housing and Fertility

POLICY

Will cheap housing lead to more babies?

The connection between housing and fertility rates has a missing piece.

Renting a home 'leads to lower birth rates'

Housing, Fertility, and Tenure Choice

Housing costs affect fertility, but tenure and wealth matter:

- Earlier access to homeownership increases eventual family size (Dettling & Kearney 2025, Fazio et al. 2025)
- Easier mortgage credit raises buying and births jointly; access to larger homes matters (Hacamo 2021, Couillard 2025)

Children increase how big of a house you need. This has implications for:

- Owning: tenure segmentation
- Wealth: borrowing constraints, bequests

Physical space is key. How much does it affect fertility?

What kind of housing policy is good for natality?

→ focus on space constraints and tenure choice

This Paper

Need a framework where fertility, tenure, housing size, saving, and population are jointly determined.

Model: overlapping generations with fertility, tenure, and saving

- Idiosyncratic earnings risk and bequests.
- Rental size limits, down payments, and housing transaction costs.
- Childbirth raises housing needs and changes future housing demand.

Empirics: housing around births, birth timing, and wealth by age

Quantification: calibrate the model and study the demographic transition

- Discipline the initial economy and the decline in fertility preferences.
- Compare housing policies from the same inherited transition state.

Model

Environment

- Overlapping generations of households in one housing market
- Adult age index $a \in \{0, \dots, J\}$; survival probability s_a
 - Working age $a < a_R$; fertile window $a \in [a_F^0, a_F^1]$
 - Children do not work; they depend on their parents
- Households differ in liquid wealth, owned housing, permanent income, earnings shocks, and family composition
- Households choose:
 - **Fertility**: whether to attempt the next birth, subject to EV shocks
 - **Tenure**: rent or buy a discrete house size H_k on a housing ladder
 - **Saving**: next-period liquid wealth b_{t+1} with age-dependent borrowing limits
- Children mature stochastically; housing need depends on children at home

Preferences

n_t : children ever born; m_t : dependents before birth; $\tilde{m}_t$: after birth.

Flow utility. Preferences are increasing and concave in consumption and housing services:

$$u_t(c_t, s_t; \tilde{m}_t) = \frac{[F(c_t, s_t - \bar{h}(\tilde{m}_t)) / e(\tilde{m}_t)]^{1-\sigma}}{1-\sigma} + \psi_t \tilde{m}_t, \quad \sigma > 0.$$

Here $F_c, F_s > 0$ and $F_{cc}, F_{ss} < 0$ above the housing requirement. The scale $e(\tilde{m}_t) > 0$ is increasing in children at home and normalized by $e(0) = 1$; children bring direct benefit $\psi_t \tilde{m}_t$ and raise consumption and housing needs.

Family needs. An equivalence scale $e(\tilde{m}_t)$ and a housing requirement:

$$\bar{h}(\tilde{m}_t) = \underbrace{h_P \mathbf{1}\{\tilde{m}_t > 0\}}_{\text{first-child housing margin}}.$$

Housing services. Households either rent or own; χ scales owner services:

$$s_t = \underbrace{\mathbf{1}\{\text{own}\} \chi h_{t+1}}_{\text{owner services}} + \underbrace{\mathbf{1}\{\text{rent}\} h_t^R}_{\text{renter services}}, \quad \chi > 0.$$

- Child costs disappear after children mature.

Bequests

Terminal utility at death:

$$B(w_{t+1}^e) = \theta_0 \frac{(\theta_1 + \max\{w_{t+1}^e, 0\})^{1-\sigma}}{1-\sigma}.$$

- θ_0 governs overall bequest motive (saving level).
- θ_1 governs its sensitivity to wealth.
- Total bequeathable wealth w_{t+1}^e includes liquid wealth and the market value of housing.

Housing, Tenure, and Budget Constraints

Households choose housing inputs:

$$h_t^R \in [0, \bar{h}^R], \quad h_{t+1} \in \{0, H_1, \dots, H_K\}.$$

A household either rents ($h_t^R > 0, h_{t+1} = 0$) or owns ($h_{t+1} > 0, h_t^R = 0$).

Tenure segmentation: $\max H_k > \bar{h}^R$, so the largest homes are reachable only through ownership.

Renters ($h_{t+1} = 0$)

$$b_{t+1} = R_b [b_t + (1 - \psi^s) P_t h_t] + y_t^d(a, z_t) + T_t - c_t - r_t h_t^R, \quad b_{t+1} \geq \underline{b}_{t+1}^R.$$

Owners ($h_t^R = 0$), with prior owner stock h_t

$$b_{t+1} = R_b b_t + y_t^d(a, z_t) + T_t - c_t - (\delta_H + \tau_t^P) P_t h_{t+1} \\ - R_b P_t \mathbf{1}\{h_{t+1} \neq h_t\} [h_{t+1} - (1 - \psi^s) h_t], \quad b_{t+1} \geq \underline{b}_{t+1}^O.$$

- R_b : gross bond rate; δ_H : depreciation; τ_t^P : property tax; ψ^s : transaction cost.
- Borrowing limits depend on age and inherited debt; purchases require a down payment.

Fertility and Child Aging

- During fertile ages, households choose whether to attempt another birth, up to the maximum family size.
- An attempt succeeds with age-specific probability π_a .
- Let $d_t \in \{0, 1\}$ be the realized birth. Post-birth states are

$$\tilde{n}_t = n_t + d_t, \quad \tilde{m}_t = m_t + d_t,$$

and the first successful birth pays the one-time utility cost F_1 .

- Fertility taste shocks have scale κ_1 on the first-birth margin and κ_C on continuation margins.
- Each dependent child matures independently; the state tracks their count m_{t+1} after maturation. The total number of births satisfies $n_{t+1} = \tilde{n}_t \in \{0, 1, 2, 3+\}$.

Firms and Earnings

- Competitive firms produce with effective labor:

$$Y_t = AL_t, \quad w = A.$$

- Age- and productivity-dependent earnings:

$$y_t^d(a, z_t) = \begin{cases} (1 - \tau^{SS}) w e_a z_t, & a < a_R, \\ \varpi_t, & a \geq a_R. \end{cases}$$

- e_a is effective labor supplied over the model period at age a ; z_t combines a permanent income group and a persistent earnings shock.
- Retirees receive a pay-as-you-go pension ϖ_t financed by payroll taxes; benefits adjust each period to balance the system.

Housing Supply and Price Mapping

Housing supply:

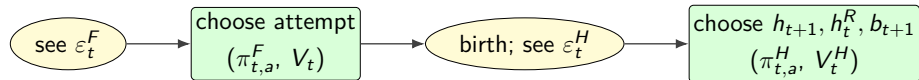

$$H_t^s = H_0 \left(\frac{P_t}{\bar{P}} \right)^\eta.$$

- H_0 : supply at reference price $\bar{P}$; η : supply elasticity.
- House prices map into user costs through

$$r_t = (R_b + \delta_H + \tau_t^P)P_t - P_{t+1}.$$

- P_t is the purchase price per room; r_t is rent per room.

The Household's Problem

State.

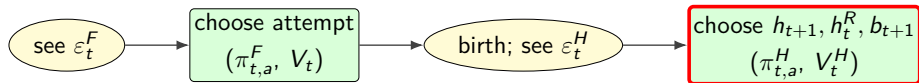

$$(b_t, h_t, z_t, a, n_t, m_t), \quad h_t \in \{0, H_1, \dots, H_K\}.$$

- b_t : liquid wealth; h_t : owner-occupied size ($h_t = 0$ if renter); z_t : earnings; a : age.
- n_t : fertility; m_t : children at home.
- After the birth outcome, $\tilde{n}_t$ is the period's fertility state; if no birth, $\tilde{n}_t = n_t$.

Within the period: choose whether to attempt a birth, then $(h_{t+1}, h_t^R, b_{t+1})$.

A renter sets $h_{t+1} = 0$; an owner sets $h_t^R = 0$.

The Household's Problem: Housing and Saving

Conditional on the realized family size:

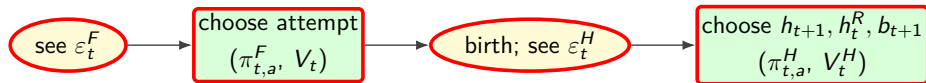

$$V_t^H(b_t, h_t, z_t, a, \tilde{n}_t, \tilde{m}_t) = \mathbb{E}_{\varepsilon_t^H} \max_{h_{t+1}, h_t^R, b_{t+1}} \left\{ u_t(c_t, \chi h_{t+1} + h_t^R; \tilde{m}_t) + \varepsilon_t^H(h_{t+1}) \right. \\ \left. + \beta \mathbb{E}_t[s_a V_{t+1}(b_{t+1}, h_{t+1}, z_{t+1}, a + 1, n_{t+1}, m_{t+1}) + (1 - s_a)B(w_{t+1}^e)] \right\}.$$

- Owner stock $h_{t+1} \in \{0, H_1, \dots, H_K\}$; rental flow $h_t^R \in [0, \bar{h}^R]$.
- Adjustment indicator $\tau_t = \mathbf{1}\{h_{t+1} \neq h_t\}$.

Budget and collateral.

$$c_t + b_{t+1} + r_t h_t^R + (\delta_H + \tau_t^p) P_t h_{t+1} = R_b b_t + y_t^d(a, z_t) + T_t - R_b \tau_t P_t [h_{t+1} - (1 - \psi^s) h_t], \\ b_{t+1} \geq \underline{b}_{t+1}^R \quad (h_{t+1} = 0), \quad b_{t+1} \geq \underline{b}_{t+1}^O \quad (h_{t+1} > 0).$$

The Household's Problem: Fertility Choice

At $(b_t, h_t, z_t, a, n_t, m_t)$, waiting and attempting have values

$$\begin{aligned}
 W_t^0 &= V_t^H(b_t, h_t, z_t, a, n_t, m_t), \\
 W_t^A &= \pi_a [V_t^H(b_t, h_t, z_t, a, n_t + 1, m_t + 1) - F_1 \mathbf{1}\{n_t = 0\}] \\
 &\quad + (1 - \pi_a) V_t^H(b_t, h_t, z_t, a, n_t, m_t).
 \end{aligned}$$

Before fertility tastes, household value is

$$V_t(b_t, h_t, z_t, a, n_t, m_t) = \mathbb{E}_{\varepsilon_t^F} \max\{W_t^0 + \varepsilon_{t,0}^F, W_t^A + \varepsilon_{t,A}^F\}.$$

Choice probabilities:

$$\pi_{t,a}^F(b_t, h_t, z_t, n_t, m_t) = \frac{\exp\{W_t^A/\kappa(n_t)\}}{\exp\{W_t^A/\kappa(n_t)\} + \exp\{W_t^0/\kappa(n_t)\}},$$

Here $\kappa(n_t) = \kappa_1$ if $n_t = 0$ and κ_C otherwise. Expected births equal $\pi_a \pi_{t,a}^F$.

Population and Households

Births change future housing demand by changing the number and age of households.

- $N_t = N_{t,0}$: resident persons at the start of period t , tracked by age and sex.
- H_t : household heads, obtained from persons using age–sex headship rates.
- G_t : the distribution of household wealth, earnings, tenure, and children.

Births enter the population immediately. Survival, migration, and household formation determine when they add to housing demand.

Equilibrium

An equilibrium is a sequence of policy functions, value functions, household distributions, populations, prices, transfers, and pensions such that:

1. Given prices, fiscal paths, and expectations, policies solve the household's problem and values give the associated lifetime utilities.
2. Within period t , annual steps j and fixed headship rates satisfy:

$$N_{t,j+1} = A_{t,j+1}N_{t,j} + f_{t,j+1}B_{t,j+1} + M_{t,j+1},$$
$$H_{t,j}^{g,\ell} = \rho^{g,\ell} N_{t,j}^{g,\ell}, \quad N_{t+1,0} = N_{t,L}.$$

Fertility determines B ; A ages survivors, fB counts newborn survivors, and M is net migration. L counts annual steps; ℓ is age in years.

3. From the initial state, distributions follow policies, idiosyncratic shocks, and demographic entry and exit, with $\int dG_t = H_t$, the head count over represented adult ages.
4. Housing clears, $\int q_t dG_t = H_t^s$, with q_t measured in physical rooms. Asset pricing and the pay-as-you-go pension rule hold.

Empirics

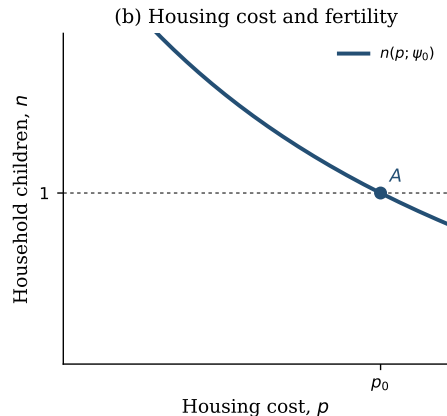

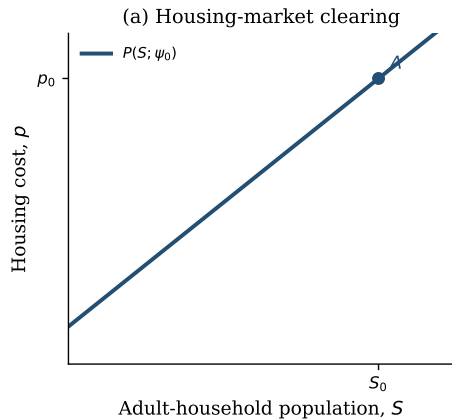

Housing and Fertility in Equilibrium

For intuition, think of fertility as a function of housing costs.

- **Left panel:** $P(S; \psi)$ is the housing cost that clears the market at adult-household population S , holding age composition fixed.
- **Right panel:** $n(p; \psi)$ summarizes the fertility response to housing cost p and fertility preference ψ .
- The illustration uses a closed population, with replacement equal to $n = 1$.

In the full model, fertility also depends on household states and expected prices. Here p summarizes housing costs.

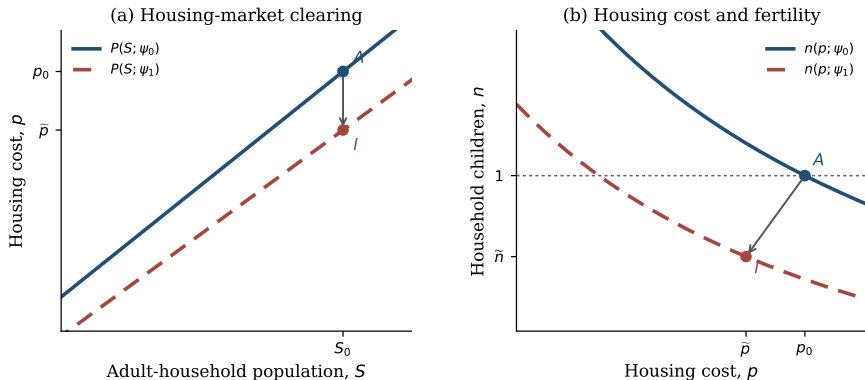

Initial Steady State

At A, housing clears at (S_0, p_0) and fertility is at replacement.

The housing cost and population are constant in this schematic initial economy.

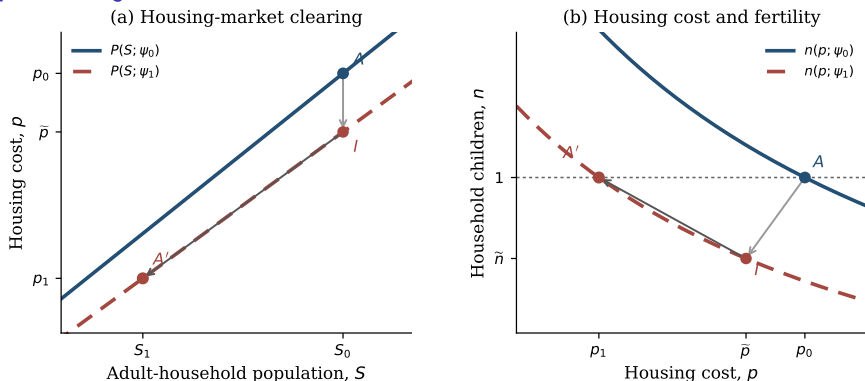

Impact

A fall from ψ_0 to ψ_1 shifts both schedules. With S_0 inherited, the schematic impact equilibrium moves from A to I : housing cost and fertility fall.

The diagram shows a one-time shift; the quantitative preference decline is spread over time.

Demographic Adjustment

Smaller entering cohorts can reduce housing demand. Lower housing costs partly offset the preference decline; A' marks a possible stationary outcome.

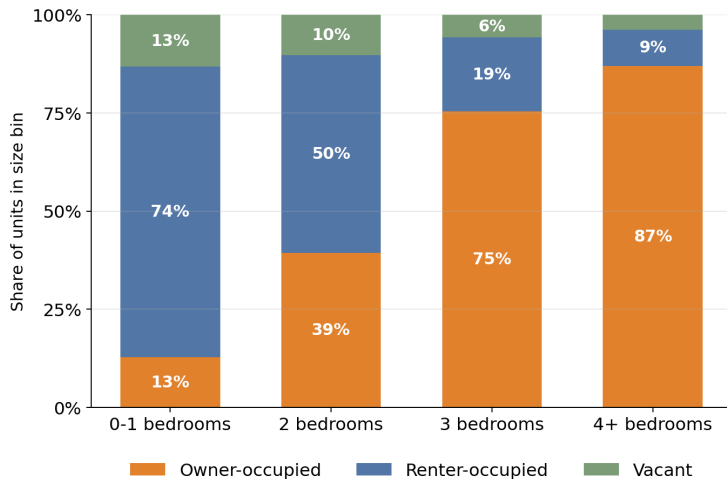

The arrow links the illustrated equilibria. Changing age composition can produce overshooting; it is not a computed transition or a convergence result.

Data

- **AHS and ACS:** housing sizes, tenure, household composition, and age profiles.
- **PSID:** housing around childbirth, earnings, and wealth by age.
- **CPS and natality records:** completed fertility, childlessness, and birth timing.
- **Census population estimates:** age–sex population and demographic flows.

Cross-sectional housing patterns discipline access to space; longitudinal data describe housing adjustment around births.

Quantification

Calibration and Historical Transition

1. Calibrate the 2007 steady state.

Match fertility, housing, and wealth moments to determine household parameters.

2. Estimate the sequence of fertility shocks.

Hold those parameters fixed and match birth rates through 2023 with unanticipated changes in fertility preferences. Carry households and population forward between shocks.

3. Project the economy forward.

After 2023, hold fertility preferences fixed and solve for prices, housing choices, and population. Compare housing policies from the same 2023 economy.

Utility Specification

For quantification, use the following functional form:

$$u_t(c_t, s_t; \tilde{m}_t) = \frac{\left[\frac{c_t^{\alpha_0} (s_t - \bar{h}(\tilde{m}_t))^{1-\alpha_0}}{e(\tilde{m}_t)} \right]^{1-\sigma}}{1-\sigma} + \psi_t \tilde{m}_t.$$

$$e(\tilde{m}_t) = \left(\frac{2 + 0.7\tilde{m}_t}{2} \right)^{0.7}, \quad \bar{h}(\tilde{m}_t) = h_P \mathbf{1}\{\tilde{m}_t > 0\}, \quad \alpha_0 = 0.733, \quad \sigma = 2.$$

Historical Fertility Discipline

Choose each preference level to match fertility over the following four calendar years.

Decision date	Birth years	Mean published TFR
2007	2008–2011	1.9749
2011	2012–2015	1.8610
2015	2016–2019	1.7554
2019	2020–2023	1.6458

The model sums age-specific births per adult household: an approximate analogue of female period TFR. The exposure mapping remains to be reconciled.

This is the estimation design. A complete historical fit requires converged conditional equilibria and stability to a longer continuation horizon.

Source: Published annual U.S. total fertility rates; equal-weight four-year averages.

Empirical Discipline

Moments inform parameters through their joint effects on household choices.

Margin	Empirical variation	Parameters
Fertility	Childlessness and one-child families; mean first-birth age and the share at age 30+	F_1, κ_1, κ_C
Housing	Rooms and ownership; housing around first birth and differences across family sizes	h_P, χ, H_0
Saving	Wealth relative to earnings, bequest flows, and old-age wealth dispersion	$\beta, \theta_0, \theta_1$

Fertility stocks and birth timing discipline different margins. Housing around birth informs demand for space.

Moment Construction

Compare model moments with the same age windows, conditioning events, and time units used in the data.

- **Fertility:** CPS 2004/2006 children ever born at ages 40–44; natality records 2003–2006 for first-birth timing. Interpolate birth timing within model age cells.
- **Housing:** ACS 2005/2006, pooled across 42 metros; match room top-codes, age ranges, and resident-child groups. The model uses dependent counts as the child-group proxy.
- **Wealth:** PSID 2003/2005; match weighted wealth/earnings and old-age wealth/income dispersion. Bequests/wealth is an external flow restriction.
- **Housing around birth:** compare a longitudinal PSID room response with the corresponding model event contrast; the empirical timing and reference design remain under review.

Calibration: Targets and Model

Moment	Target	Model
Completed fertility (normalization)	2.10	2.10
Childless, women 40–44 (%)	19.8	20.7
Exactly one child among mothers, 40–44 (%)	21.4	20.7
Mean age at first birth (years)	25.98	26.10
First births at age 30+ (%)	24.9	23.2
Mean occupied rooms (capped at 9)	5.56	6.29
Ownership, heads 30–55 (%)	64.8	52.4
First-birth room response, -1 to $+3$	0.720	1.011
Rooms: 3+ versus 1–2 resident children	0.347	0.200
Recent-parent ownership gap (pp)	16.3	15.0
Wealth / annual gross earnings	6.15	4.85
Annual bequests / wealth (%)	0.88	0.86
Wealth/income p90 / median, ages 76–84	3.52	4.44

Calibrated Parameters

Parameter	Economic interpretation	Value
β_{annual}	Annual discount factor	0.990
κ_1	First-birth taste dispersion	0.279
κ_C	Later-birth taste dispersion	0.347
χ	Owner housing-service multiplier	1.048
H_0	Housing supply at reference price	8.191
θ_0	Bequest-motive scale	0.087
θ_1	Bequest-utility wealth shift	0.057
F_1	First-birth utility cost	0.127
h_P	Parenthood space requirement	2.300

β_{annual} and h_P reach their upper search bounds.

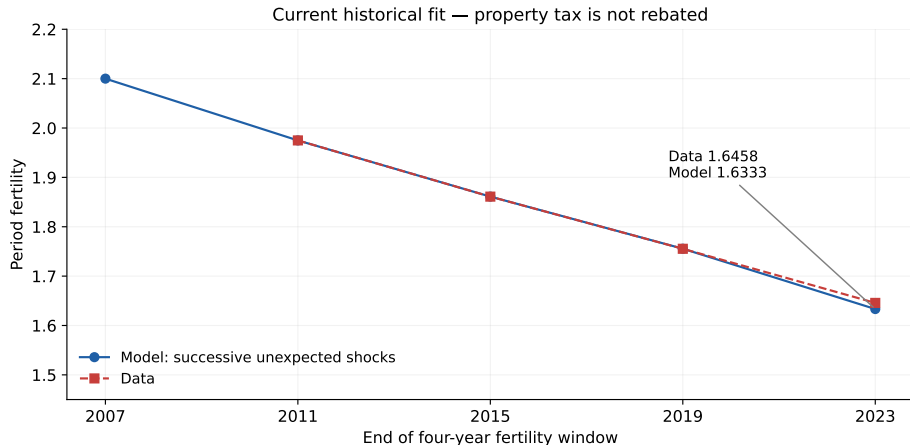

► Parameter restrictions

External Inputs and Normalizations

Parameter	Value	Source
Risk aversion σ	2	
Equivalence scale $e(\tilde{m}_t)$	$((2 + 0.7\tilde{m}_t)/2)^{0.7}$	Scholz, Seshadri & Khitatrakun (2006)
Consumption share α_0	0.733	CEX childless cash renters, 2019–2023
Housing-supply elasticity η	0.63	
Housing-taste dispersion κ_H	0.005	
Annual real return i_{ann}	2.0%	Greaney et al. (2025)
Payroll tax rate τ^{SS}	17.9%	OECD U.S. average
Initial fertility preference ψ_0	0.1596	Completed fertility of 2.1

A model period contains $L = 4$ calendar years, $\beta = \beta_{\text{annual}}^4$.

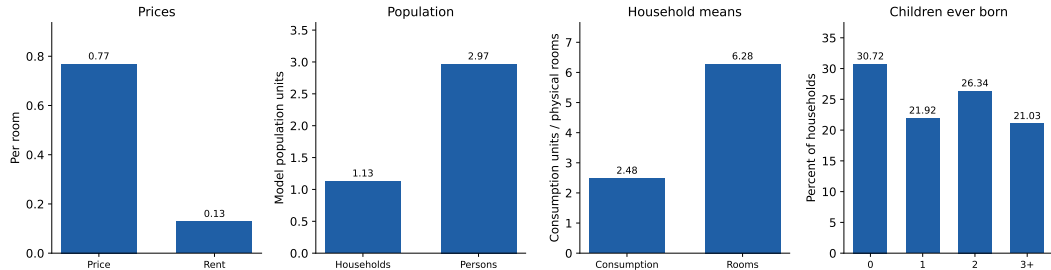

Historical Fertility

Actual household history carried forward; six-date forecasts. Final fertility target and horizon checks remain open.

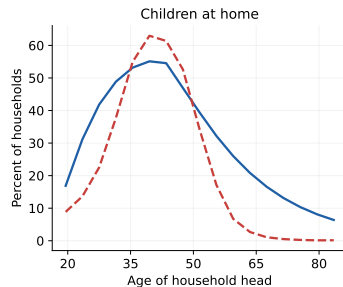

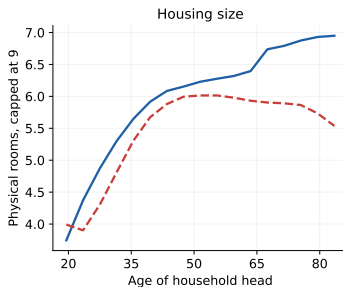

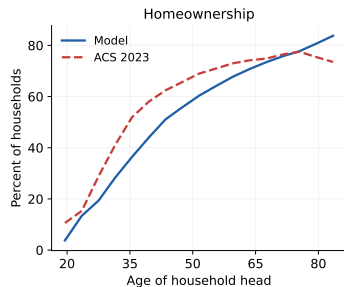

Provisional no-rebate carried history; the last window remains outside the fit tolerance, and no horizon certificate is available.

The 2023 Equilibrium

Population levels and age composition are externally conditioned.

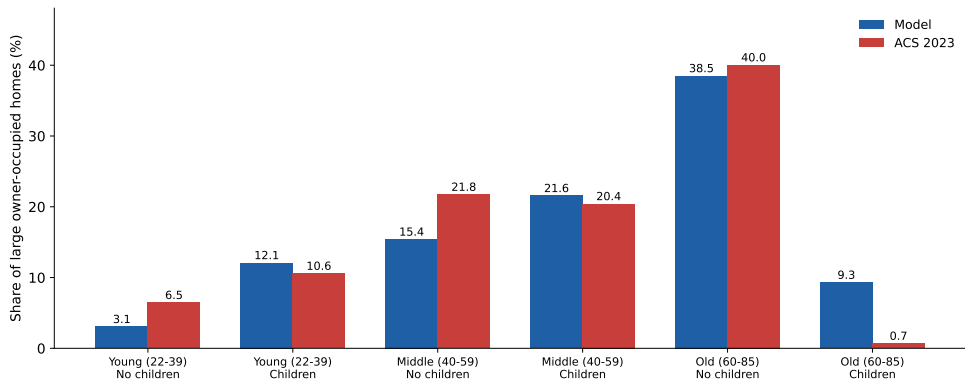

Lifecycle Fit in 2023

Children at home: model dependents; ACS resident own children under 18.

2023 profiles are untargeted comparisons; the calibration uses initial-period moments.

Intergenerational Allocation: Model vs Data

Owner-occupied homes with 6+ rooms; ACS 2023. Children: model dependents; ACS resident own minors.

Stationary Housing Policy Comparisons

Compare three stationary equilibria under the same household parameters and fertility preference:

1. Annual property tax of 1%, with no rebate.
2. Annual property tax of 1%, with an equal rebate per household.
3. Annual property tax of 2%, with an equal rebate per household.

In the rebated cases, all property-tax revenue is returned to households. Payroll taxes separately finance pensions in each equilibrium.

Conditional on the diagnostic demographic and entry assumptions; these are stationary comparisons, not transition effects from 2023.

Stationary Policy Results

	1% tax	1% tax	2% tax
	No rebate	Equal rebate	Equal rebate
Period fertility	1.7298	1.8011	1.8080
Homeownership (%)	66.31	66.13	66.80
Rooms per household	6.734	6.626	6.298
House price per room	0.633	0.707	0.659
Rent per room, per period	0.105	0.117	0.136
Rebate per household, per period	0.000	0.187	0.332
Fertility change vs. no rebate (%)	0.00	+4.12	+4.52

With rebates in both cases, raising the tax from 1% to 2% increases fertility by 0.38%.

Conditional stationary comparisons under the same demographic and entry assumptions.

Conclusion

- Children raise demand for rooms; rental size and down payments govern access to that space.
- Tenure, saving, and fertility interact over the household lifecycle.
- Births change population and housing demand with long delays.
- Property taxes and rebates jointly change housing costs and household resources.

The stationary comparisons hold demographic and entry assumptions fixed.

Thank You

Appendix

1. Calibrating the Initial Economy

Goal: fit pre-2007 household moments. External inputs and all 12 targets and weights stay fixed.

1. **Try a parameter vector θ :** nine coefficients governing saving, fertility, housing, and bequests.
2. **Compute initial age-earnings shares** from survival, entry, and the earnings process. Set the pension to payroll revenue divided by retiree exposure; verify it against the solved distribution.
3. **Try a fertility preference ψ_0 and solve the housing equilibrium.** Guess the house price P , derive rent, solve household choices backward, and find the stationary distribution forward. Update P and repeat until housing demand equals supply.
4. **Update ψ_0 with a bracketed scalar search.** Repeat step 3 for each trial until model completed fertility equals 2.1 (within 0.0005).
5. **Score this parameter vector:** compute all 12 model moments and the weighted sum of squared model-target gaps.
6. **Update θ .** Perturb each coefficient to estimate how the moments respond; use these slopes for bounded, ridge-regularized joint steps. Redo steps 2–5 for each proposal, keep the lowest loss, and repeat within the search budget. Re-solve the selected winner twice.

Nested loops: parameter search $\longrightarrow$ fertility normalization $\longrightarrow$ housing-market clearing.

2. Fitting the Historical Transition

Hold the nine structural parameters fixed. Form 2007 age masses from data; within each age, keep the calibrated distribution of wealth, housing, and family states.

1. **Try ψ_{2007} , believed permanent.** Solve the terminal stationary economy at this preference level.
2. **Guess future price and pension paths.** Solve household choices backward from the terminal value; simulate household and person distributions and birth cohorts forward from the inherited 2007 state.
3. **Update the price and pension paths and repeat step 2** until housing clears and the payroll budget balances at every date. Verify the population accounting, recompute the path, and check a longer horizon.
4. **Change ψ_{2007} and repeat steps 1–3** until first-window fertility matches the 2008–2011 target of 1.974875 (error at most 0.005). Every trial starts from the same 2007 state.
5. **Advance only after acceptance.** Keep the first four-year outcome and birth queues. Repeat at 2011, 2015, and 2019 to target the following four years. Each new preference level is unanticipated.

After 2023, hold the final preference level fixed.

The household-rate analogue of female TFR is approximate; the complete history is not yet validated.

Borrowing Limits

After a housing transaction, liquid wealth is

$$\tilde{b}_t = b_t + \mathbf{1}\{h_{t+1} \neq h_t\}[(1 - \psi^s)P_t h_t - P_t h_{t+1}].$$

Let D_{a+1} be the unsecured borrowing allowance and λ_{a+1} govern repayment of inherited unsecured debt. Its lower bound is

$$\mathcal{L}_{a+1}(u) = \min\{\lambda_{a+1} \min(u, 0), -D_{a+1}\}.$$

With collateral floor $C_t = -\phi P_t h_{t+1}$, saving must satisfy

$$\text{Renters: } b_{t+1} \geq \underline{b}_{t+1}^R = \mathcal{L}_{a+1}(\tilde{b}_t),$$

$$\text{Owners: } b_{t+1} \geq \underline{b}_{t+1}^O = C_t + \mathcal{L}_{a+1}(\tilde{b}_t - C_t).$$

A purchase ($h_{t+1} > 0$, $h_{t+1} \neq h_t$) separately requires

$$b_t + (1 - \psi^s)P_t h_t \geq (1 - \phi)P_t h_{t+1}.$$

Inherited unsecured debt can run off gradually, including for renters.

Parameter Restrictions

Parameter	Value	Lower	Upper	Position
β_{annual}	0.9900	0.94	0.99	Upper bound
κ_1	0.2794	0.02	50	Near lower bound
κ_C	0.3469	0.02	50	Near lower bound
χ	1.0480	0.1	5	Interior
H_0	8.1905	0.2	80	Interior
θ_0	0.0870	0	8	Interior
θ_1	0.0571	0.02	16	Near lower bound
F_1	0.1268	0	8	Interior
h_P	2.3000	0.1	2.3	Upper bound

Near-bound means within 1% of the allowed range; it does not establish a binding constraint. Fixed, normalized, and budget-derived objects are listed separately in the main table.

Steady-State Equilibrium

A steady state is a constant allocation, population structure, and price:

$$(N^*, H^*, G^*, \pi^*, P^*, r^*, T^*, \varpi^*).$$

Households optimize, persons and household distributions reproduce themselves, housing clears, and the fiscal rule holds.

- With no migration, births must replace deaths in a constant population.
- With migration, births and net inflows together offset deaths.
- A constant continuation value alone does not make a finite path stationary.

The Person-Cohort Law

t indexes household periods; $j = 0, \dots, L$ indexes years within each period. $N_{t,j}^{g,\ell}$ counts persons of sex g and age ℓ in years.

For $j = 0, \dots, L - 1$, the annual person law is

$$N_{t,j+1} = A_{t,j+1}N_{t,j} + f_{t,j+1}B_{t,j+1} + M_{t,j+1}.$$

- $A_{t,j+1}$ ages existing cohorts using destination-age survival.
- $f_{t,j+1}B_{t,j+1}$ allocates newborn survivors by sex at age zero.
- $M_{t,j+1}$ is the age–sex net-migration flow after survival.
- Model-period births are assigned to calendar cohorts before the annual law is iterated.

The period boundary satisfies $N_{t+1,0} = N_{t,L}$; write $N_t = N_{t,0}$.

The Household-Head Law

Annual age–sex headship rates $\rho^{g,\ell}$ map persons into the target head stock:

$$H_{t,j+1}^{g,\ell} = \rho^{g,\ell} N_{t,j+1}^{g,\ell} = H_{t,j+1}^{\text{surv},g,\ell} + F_{t,j+1}^{g,\ell} - D_{t,j+1}^{g,\ell} + H_{t,j+1}^{M,g,\ell}.$$

Aggregating annual ages ℓ into household age cells a , the household operator supplies $\tilde{G}_{t+1,a}$. Its mass is rescaled to the person-law head target:

$$G_{t+1,a}(x_{t+1}) = H_{t+1,a} \frac{\tilde{G}_{t+1,a}(x_{t+1})}{\int \tilde{G}_{t+1,a}(\xi) d\xi}.$$

- F and D are the minimum one-way formation or dissolution flow needed to attain $\rho^{g,\ell}$.
- Wealth, tenure, income, and family composition are preserved within age.
- This is an accounting closure, not an estimated household-formation hazard.

Exact Annual Person Accounting

Let $s^{g,\ell}$ be survival and f^g the birth sex share. For newborns,

$$N_{t,j+1}^{g,0} = s_{t,j+1}^{g,0} f_{t,j+1}^g B_{t,j+1} + M_{t,j+1}^{g,0}.$$

For interior ages $\ell \geq 1$,

$$N_{t,j+1}^{g,\ell} = s_{t,j+1}^{g,\ell} N_{t,j}^{g,\ell-1} + M_{t,j+1}^{g,\ell}.$$

The terminal age is top coded, so survivors from the penultimate and terminal cells both enter the last cell. Every step satisfies

$$\sum N_{t,j+1} = \sum N_{t,j} + B_{t,j+1} - \text{newborn deaths} - \text{existing deaths} + \sum M_{t,j+1}.$$

The Within-Age Household Bridge

Let $\tilde{G}_{t+1,a}(x_{t+1})$ be the raw household transition within age a , and let $H_{t+1,a}$ be the head mass implied by persons. Then

$$G_{t+1,a}(x_{t+1}) = \begin{cases} H_{t+1,a} \frac{\tilde{G}_{t+1,a}(x_{t+1})}{\int \tilde{G}_{t+1,a}(\xi) d\xi}, & \int \tilde{G}_{t+1,a} > 0, \\ H_{t+1,a} \Gamma_a(x_{t+1}), & \text{for an empty entrant age cell,} \end{cases}$$

where Γ_a is the externally specified entrant template. The operation exposes added and removed mass separately and moves no mass across ages.

A richer model would estimate economic states for newly formed, dissolved, and migrant heads rather than preserve the raw conditional composition.

Housing-Market Clearing

Let $q_t(x_t)$ denote the physical housing occupied after tenure choice. Market clearing requires

$$Q_t^H = \int q_t(x_t) dG_t(x_t) = H_0 \left(\frac{P_t}{\bar{P}} \right)^\eta.$$

For renters, $q_t = h_t^R$; for owners, $q_t = h_{t+1}$. Choice probabilities are included when aggregating.

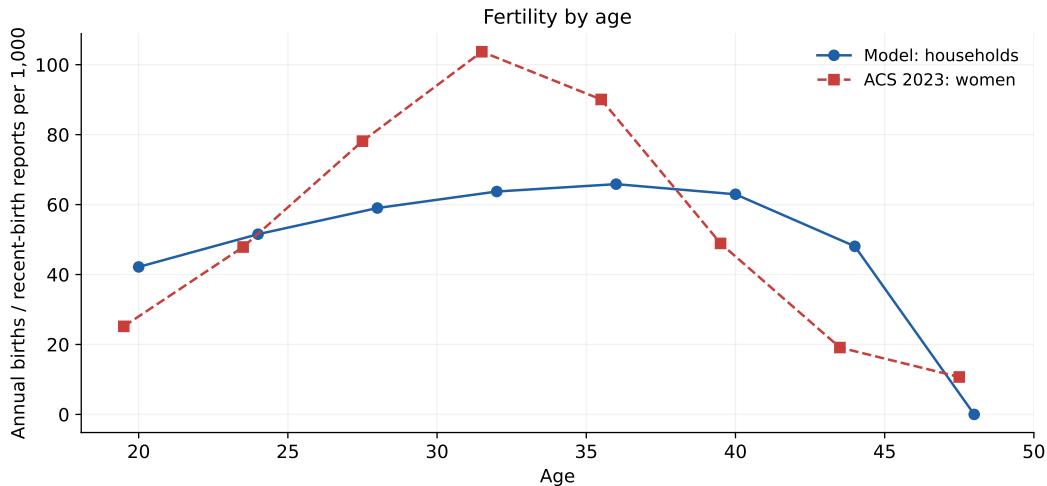

- The owner-service premium changes utility, not physical supply.
- Conditional renter policies enter demand only when renting is chosen.
- The same supply schedule applies to baseline and tax-reform paths.

Perfect-Foresight Solution

1. Guess the price and pension paths and compute rents from asset pricing.
2. Solve households backward using date-specific continuation values.
3. Advance household and population distributions from the inherited state.
4. Update prices and pensions until housing clears and the payroll budget balances at every date.
5. Extend the horizon and check that the measured outcomes are stable.

A stationary terminal value supplies a boundary condition; it does not establish stationarity of the simulated endpoint.

Fertility by Age: Measurement Comparison

Model: annualized 2023-2027 birth flow. ACS: women reporting a birth in the previous 12 months.

Prices and Quantities Along the Finite Path
