

Housing allocation across generations

A simple argument and its extensions

Discussion note for Tommaso De Santo September 5, 2026

1. The question

Can borrowing limits and restricted rental housing leave too much of the existing housing stock with older households? The useful claim is that a young household may value additional space more than an older owner values keeping it. A small reallocation can then improve welfare while leaving fertility unchanged. We can establish this before discussing a policy.

Households and preferences. Take an equilibrium of the existing two-period OLG model. At each date there are young and old households, with an infinite succession of cohorts. Young households choose consumption, housing, completed fertility, saving, and tenure. Their flow utility and the old household's flow utility remain:

$$u_t^Y(c, h, n) = \log(c - \chi n) + \alpha \log(h - \kappa n) + \vartheta_t \log n, \quad (1)$$

$$u^2(c^2, h^2, e) = \log c^2 + \gamma \log h^2 + \omega_B \log e. \quad (2)$$

Each child uses χ goods and κ housing; e is the warm-glow estate. Old-age utility is discounted by β ; ownership adds the taste ξ_i . The original lifetime value functions W_t^m and old-age value functions V_t^m retain their definitions. Write $x = c - \chi n$ and $s = h - \kappa n$ for the goods and space available to adults.

Housing and finance. The fixed housing stock is $\bar{H}$. Rental homes satisfy $h \leq h_R^{\max}$, and owner homes satisfy $h \leq h_O^{\max}$, with $h_R^{\max} < h_O^{\max}$. A mortgage finances the share ϕ of the purchase. A young buyer with liquid wealth b_i must meet:

$$(1 - \phi)P_t h \leq b_i. \quad (3)$$

Only liquid wealth is available at closing. Income and ordinary rebates arrive later. Old owners can sell part of their homes, but cannot buy more or let their retained housing. The original saving, retention, and estate restrictions remain part of the household problems.

Households save in a world bond priced at q . There is no capital-gains tax in this core. The ordinary property-tax rate is τ^p , so the current value of one unit of rent is:

$$u_t = qr_t = (1 + q\tau^p)P_t - qP_{t+1}. \quad (4)$$

This is the cost of using a unit of housing for the period, including its subsequent resale value.

The comparison. Hold each household's fertility and tenure fixed. The direct planner may relax private financing limits, as already agreed, while respecting the housing stock, physical tenure restrictions, and real resources. We compare each household's lifetime welfare, including the initial old and all future cohorts. The construction below leaves every future real allocation unchanged.

2. The short allocation argument

Consider a young owner i and an old owner j . Their willingness to give up current consumption for an additional housing unit is:

$$MV_i^Y = \frac{\alpha x_i}{s_i}, \quad MV_j^O = \frac{\gamma c_j^2}{h_j^2}. \quad (5)$$

These are marginal rates of substitution, expressed in the same goods units. They do not compare raw marginal utilities across people.

Proposition 1 (Housing misallocation). *Suppose a positive mass of young owners can physically occupy more housing and a positive mass of old owners can release some. If, on matched groups, $MV_i^Y > MV_j^O$, a sufficiently small owner-to-owner reallocation can make young households better off and leave everyone else equally well off, holding fertility fixed. The benchmark admits direct goods compensation and financial settlement while relaxing private financing restrictions. Reallocation has no additional real cost.*

Proof. Select equal-mass groups with a strict value gap and room for a small change. Transfer ϵ housing per household from old to young. The old household requires the following extra consumption to retain its utility:

$$D_j(\epsilon) = c_j^2 \left[\left(\frac{h_j^2}{h_j^2 - \epsilon} \right)^\gamma - 1 \right]. \quad (6)$$

Give it this amount from the young household's current consumption. Goods and housing balance exactly. The young household's utility change is $\log(1 - D_j(\epsilon)/x_i) + \alpha \log(1 + \epsilon/s_i)$; its derivative at zero is $(MV_i^Y - MV_j^O)/x_i > 0$. Small changes preserve positive consumption and physical feasibility. Estates, future consumption and occupancy, and all other households' allocations stay fixed. Title settlement replaces the old seller's lost estate title with an equal bond claim; the young buyer's later sale of the extra title offsets its financing. Existing creditors and the aggregate external-asset position are unchanged. $\square$

Figure 1. A compensated reallocation in Appendix A's equilibrium, holding old utility fixed. Shading marks the value gap; its area is not a welfare measure. Equal values maximize the young household's gain along this comparison, without solving the economy's full first best.

3. Why the constraints matter

The borrowing limit creates the value gap. In the case we have been studying, young owners save a positive amount, their physical housing limit is slack, and their old-age retention and estate constraints are slack. If the purchase limit strictly restricts housing, their optimal choices imply $MV_i^Y > u_t$. An old owner with slack retention and estate constraints has $MV_j^O = u_t$. The equilibrium therefore supplies the strict inequality used in Proposition 1. Appendix A constructs mixed-tenure steady states satisfying these conditions; they are not empty assumptions.

The proposition itself needs only the actual value gap and feasible compensation. If another household constraint binds, compare the two values in (5) directly. The special equality to user cost may then fail.

The rental restriction limits an alternative way to obtain space. A young family may be unable to rent the home it wants, and unable to fund the down payment on a larger owned home. This is a useful account of housing access. The local proof, however, transfers housing between owners and leaves rental housing unchanged. A renter at a physical size cap cannot receive more space under the same tenure when the planner must respect that cap. Its high housing value alone is therefore insufficient to prove misallocation.

An ownership taste matters for this interpretation. The original model gives households a taste ξ_i for ownership. With a sufficiently positive taste, a household may prefer constrained ownership even if larger rentals are available. Indeed, Appendix A gives an equilibrium with slack rental limits and a strict owner value gap. Removing the redundant rental limit leaves that equilibrium unchanged. Both constraints need not bind for the owner-to-owner inefficiency to exist. There is a useful elementary comparison if we want both access restrictions to be essential. Suppose an owner receives no ownership-taste benefit, and the rental menu contains its current and old-age housing choices. Its entire owner allocation can be reproduced by renting and choosing financial saving:

$$a'_R = a'_O + qP_{t+1}h - \phi P_t h. \quad (7)$$

Substituting (4) into the original budgets verifies both dated budgets exactly. If this saving is nonnegative and the current rental cap leaves room, a household with $MV_i^Y > u_t$ can then improve by renting a little more space. Such a household would not choose constrained ownership without an ownership benefit. Rental segmentation can prevent that alternative. Removing the ownership taste would make this joint role sharper, but would be a separate model choice, not a notation change.

What OLG adds. Young households need purchase cash while old owners already hold titles. Housing needs and financial positions differ over life, and the same stock passes through successive cohorts. The local proof remains a simple exchange argument with fixed continuation allocations. It establishes housing misallocation without invoking capital overaccumulation or benefits from additional births.

4. A separate fertility prediction

More housing reduces the space cost of children, but paying for it leaves less for their goods costs. These effects can be separated in the original household equations.

Take the conditional household problem with positive saving and unchanged old-age constraints. At a binding housing limit, it gives:

$$(1+k)x + \chi n + uh = \tilde{w}, \quad \frac{\vartheta}{n} = \frac{\chi}{x} + \frac{\alpha\kappa}{h - \kappa n}. \quad (8)$$

Here $k = \beta(1 + \gamma + \omega_B)$ with interior old choices, and $\tilde{w} = y + b + T_t + qT_{t+1}$. If old renter housing is capped, instead use $k = \beta(1 + \omega_B)$ and subtract the discounted fixed old rent from resources.

Let p be the net lifetime payment per marginal unit of current housing. Relaxing only its cap gives $p = u_t$ at fixed prices and resources. If both binding rental caps increase equally, $p = u_t + qu_{t+1}$. Accompanying transfers also enter p . The budget gives $(1+k)dx = -\chi dn - pdh$. Substituting this into the fertility condition yields:

$$\frac{dn}{dh} = \frac{\frac{\alpha\kappa}{s^2} - \frac{\chi p}{(1+k)x^2}}{\frac{\vartheta}{n^2} + \frac{\chi^2}{(1+k)x^2} + \frac{\alpha\kappa^2}{s^2}}. \quad (9)$$

The denominator is positive. Fertility rises precisely when the space benefit in the numerator exceeds the resource cost. There is no borrowing multiplier in this condition.

A sufficient restriction in primitives. With stationary prices, zero property tax, interior old choices, and a strictly binding down-payment limit, the existing sufficient restriction is:

$$\frac{(1-q)b}{(1-\phi)(y+b)} \geq \frac{\alpha}{1 + \beta(1 + \gamma + \omega_B) + \alpha}. \quad (10)$$

It implies that a marginal increase in housing raises fertility for every $p < MV^Y$ while the stated constraints continue to bind. The left side is housing expenditure at the purchase limit relative to lifetime resources; the price cancels because the limit is inversely proportional to price. This is sufficient, not necessary, and the zero-property-tax specialization is explicit. Endogenous rebates cannot generally be treated as primitives.

Why the qualification matters. For the constructed household values $1+k=2$, $\alpha = \chi = x = s = n = 1$, $\kappa = 0.1$, $\vartheta = 1.1$, and $u = p = 0.5$, more housing improves welfare but $dn/dh = -15/161$. At $p = 0$ the derivative is $10/161$. The difference is the payment for the extra space.

This is a conditional household prediction. The fixed-fertility allocation proof holds future choices fixed; this calculation allows optimal saving and old-age choices to adjust. They are distinct comparisons. A policy also changes prices, tenure, and later cohort sizes, which must be included before claiming an aggregate fertility increase.

5. A transition to a larger population

Let Y_t and O_t count young and old households, and let $\bar{n}_t$ be mean young fertility. The parameter ν converts births into entering households. From $Y_{t+1} = \nu \bar{n}_t Y_t$, two paths with the same initial young cohort satisfy:

$$\frac{Y_t^1}{Y_t^0} = \prod_{s=0}^{t-1} \frac{\bar{n}_s^1}{\bar{n}_s^0}, \quad O_t^j = Y_{t-1}^j. \quad (11)$$

Temporary fertility differences can leave permanent population differences. The relevant object is their cumulative effect, even if fertility falls at some dates. At a positive steady state, $\bar{n}^* = 1/\nu$ and $Y^* = O^*$; housing clearing then fixes total household population:

$$N_{\text{hh}}^* = \frac{2\bar{H}}{\bar{h}Y^* + \bar{h}O^*}. \quad (12)$$

A larger population with the same stock requires less housing per household on average. Young housing may rise if old housing falls enough.

A local equilibrium result is now available. Appendix B gives an explicit condition in parameters for convergence in the all-owner limit with $\chi = \tau^p = 0$, and a separate sufficient condition for initial fertility to rise. The final population rises. With uniformly strict household choices, these results extend to small positive renter shares, child goods costs and property tax. Income and wealth can be heterogeneous. Fertility and tenure are chosen freely. The reform must be small, and the allowed positive-parameter neighborhood has not been numerically bounded.

Figure 2. The analytical first-order equilibrium response in Appendix B’s limiting economy, per unit increase in $d = b/(1 - \phi)$. The curves come from the derived path, not a prescribed fertility sequence. Fertility rises most in the second young cohort. These illustrative parameters are not a calibration.

In the limiting economy, sufficiently small finite reforms also raise fertility above replacement at every date, and population rises monotonically. For the nearby mixed economies, the proved signs are initial fertility and final population; an all-date sign is a separate question. Appendix C gives a primitive condition for the stationary population sign when $\chi > 0$.

The stationary ranking also applies to persons when adults per household and child-counting rules are unchanged. During adjustment, resident children must also be counted. A stock increase has a simpler stationary comparison: multiplying $\bar{H}$ by a scales every cohort by a at unchanged individual choices, prices, and rebates under the existing external-income closure.

6. Constrained efficiency and public finance

The basic result already identifies misallocation. Proposition 1 exhibits a feasible allocation that improves welfare. It respects physical housing restrictions and relaxes private finance. It neither characterizes the full first best nor requires a government lending policy.

A constrained comparison asks an additional question. Can an authority improve welfare using a specified set of instruments while households continue to choose at clearing prices? The restrictions on the authority must be stated before answering. Retaining the private mortgage formula while allowing public credit is a different comparison from retaining the household's effective financing opportunities. Bisin's lecture notes, section 3.2.4, make the choice of constrained feasible allocations explicit.

The current research contains two results with different scopes:

- A complete local improving path under committed household-specific payments when young and old, enforceable future taxes, and explicit initial title ownership with access to finance. Fertility is fixed individually. Every market clears, but the path returns to the original steady state.
- An obstruction to one initial round of transfers near one studied stationary regime, for nearby converging paths on the maintained household branches. This does not establish efficiency under every other transfer class.

These results remain useful background. The second does not show that public loans are the only possible remedy. The first supplies financing across a household's life and should be described accordingly. Neither is required for the short allocation argument.

The loan interpretation is a later extension. For later cohorts, the committed-transfer construction advances purchase cash and collects repayment plus part of the household's housing gain. A government with access to world bonds could potentially replace the separate financier. All original property claims and promised estate payments would still need to be honored. A voluntary loan programme also changes participation and tenure choices; its proof is not obtained just by relabeling identity-based transfers.

There are established precedents for the broad financing role. Auerbach and Kotlikoff's compensation authority balances in present value; their payments to future households occur on entry. Schoonbroodt and Tertilt use public transfers to overcome parent-child transfer restrictions. With binding liquidity constraints, the timing and eligibility of our proposed payments remain substantive adaptations.

Recommendation. Use "housing misallocation" for the core result. Retain constrained efficiency as an optional strengthening under a precisely defined benchmark. Discuss public financing after deciding whether that strengthening adds enough to justify its assumptions and length.

References for these distinctions: Bisin (2014), lecture notes, section 3.2.4; Auerbach and Kotlikoff (1987), chapter 5, B.3, pp. 62–64; Schoonbroodt and Tertilt (2014), sections 5.2–5.3. These sources motivate the comparisons; our housing claims require the model-specific proofs.

7. Assessment and opportunities

The core is ready to be stated simply. A financial restriction can prevent a young household from obtaining housing it values more than an old owner does. A direct reallocation with consumption compensation establishes the welfare content. The proof takes a paragraph. Its role is to define the misallocation and explain the first figure. There is no need to present it as an unusual welfare theorem.

The useful clarification concerns tenure. Rental segmentation helps explain why a household cannot obtain its preferred space by renting. Yet the ownership taste allows the borrowing distortion to persist without a binding rental cap. The existing model supports the statement that the two restrictions can coexist with misallocation. It does not support the claim that both are necessary. The replication argument on page 3 shows how removing the ownership taste could sharpen their joint role, at the cost of a model change.

My recommendation is to retain the present model for the first pass. Preserve its notation and household problems, and state the allocation result. Removing ownership tastes is an alternative to consider only if the paper's message requires both access restrictions to be essential.

The extensions have different value and cost:

- **Real reallocation costs: keep compact.** If $C(0) = 0$ and $C'(0) = K$, replace the condition by $MV_i^Y > MV_j^O + K$. A positive fixed moving cost requires a finite transfer; the exact compensation formula supplies the test. Compensation paid to the seller is not itself a real resource cost.
- **Fertility: retain as a separate conditional prediction.** Equation (9) expresses the space benefit and resource cost directly. The primitive restriction is available as a sufficient specialization, with its limitations stated once.
- **Population: an analytical local transition is available.** It gives a model-implied second figure and a larger final population. The parameter conditions and local scope must stay visible. General large-reform transitions and unrestricted heterogeneity remain open.
- **Constrained efficiency: optional strengthening.** Its value depends on a natural and clearly stated instrument class. The current committed-finance proof can remain outside the short core while that choice is considered.
- **Public loans, endogenous rental supply, and gains taxation: later branches.** Each asks an additional economic question. Their detailed policy design would make the initial illustration harder to read.

Population and welfare must remain separate. The uncompensated credit reform in Appendix B lowers stationary household welfare even though it raises population. This does not contradict Proposition 1, which compensates the housing donor and holds fertility fixed. A credit reform does not implement that compensated allocation automatically.

The paper's core could occupy two or three pages after the household setup, including Figure 1. The longer transition proof can stay in an appendix.

Proposed order for discussion. Settle Proposition 1 and its allocation benchmark first, then the fertility and population extensions, then the value of retaining constrained efficiency. No preference change is adopted here.

Appendix A. The conditions can hold in equilibrium

The following construction checks that Proposition 1 can apply to positive masses of households in a mixed-tenure steady state. It chooses primitives to support an allocation directly. Income and the ownership-taste location vary across the family; this is not a tax comparative static or a calibration.

Set $P = 1$, $q = 0.5$, $\phi = 0.8$, $b = 0.2$, $\bar{H} = 2$, and $\nu = 2$. Use $\alpha = \beta = \omega_B = 0.4$, $\gamma = 0.3$, $\chi = 0.15$, $\kappa = 0.5$, $h_R^{\max} = 0.25$, and $h_O^{\max} = 2$. Choose young-owner adult consumption, housing, and fertility as $(x, h, n) = (1, 1, 0.75)$. The fertility condition sets $\vartheta = 0.3525$. For any $0 \leq \tau^p < 0.28$, user cost is $u = (1 + \tau^p)/2 < 0.64 = MV^Y$. Old-owner choices are:

$$c^2 = 0.8, \quad h^2 = 0.24/u, \quad e = 0.64. \quad (13)$$

Retention and estate bounds are strictly slack throughout this interval.

Let $w = 1.7925 + u$. With both rental caps binding, the renter's fertility is the unique root in $(0, 0.5)$ of:

$$\frac{0.3525}{n^R} = \frac{0.15}{x^R} + \frac{0.2}{0.25 - 0.5n^R}, \quad x^R = \frac{1.7925 + 0.625u - 0.15n^R}{1.56}. \quad (14)$$

The left side decreases from infinity and the right side increases to infinity. Their root has $x^R > 1.30$, which makes both rental caps strictly binding under the original housing conditions. Both tenures save positively.

Set the owner share to $\pi^O = (0.5 - n^R)/(0.75 - n^R) \in (0, 1)$, so average fertility is replacement. Define housing demand per young-old pair as $d_h = \pi^O(1 + 0.24/u) + (1 - \pi^O)0.5$. Choose $Y = O = 2/d_h$, $T = q\tau^p d_h/2$, and $y = w - b - (1 + q)T > 0$. Housing and the property-tax budget then clear exactly. With any taste scale $\sigma_\xi > 0$, choose $\bar{\xi} = \sigma_\xi \log[\pi^O/(1 - \pi^O)] - W^O + W^R$ to support the owner share under the original logistic rule. The dated budgets and first-order conditions give household optima because their feasible sets are convex and their utility is concave.

A rental cap need not bind. A second construction sets $\tau^p = 0$, $h_R^{\max} = 1.5$, and owner fertility $n^O = 0.49$, retaining $(x, h) = (1, 1)$ and the other displayed primitives. Set $\vartheta = 61397/302000$ and $y = 2.0535$. Unconstrained renter demands and the same tenure-share construction give:

	Both rental caps bind	Both rental caps slack
Property tax	0.05	0
Owner share	0.523810	0.139390
Young renter housing	0.250000	1.040368
Young owner housing value	0.640000	0.529801
Old owner housing value	0.525000	0.500000

The second equilibrium remains an equilibrium if its redundant rental limit is removed. These are two different constructed economies, not a comparison holding all primitives fixed while changing the rental cap.

Appendix B. Conditions for a local equilibrium path

Use the all-owner demand limit at a steady state with $\chi = \tau^p = 0$. Young saving is positive, purchase limits strictly restrict housing, and physical owner caps and old retention and estate constraints are slack. Entrants may differ in income and wealth if these conditions hold uniformly. Define:

$$\begin{aligned} \ell &= 1 - q, \quad A = 1 + \gamma + \omega_B, \quad \rho = 1 + \beta A, \quad D = \frac{\beta\gamma}{\rho}, \quad L = \frac{\gamma}{A}, \\ d &= \frac{E[b_i]}{1 - \phi}, \quad w = E[y_i + b_i], \quad r = \frac{w}{d}, \quad C = \frac{D(r - \ell)}{q\ell}. \end{aligned}$$

All these quantities are computed from primitives. Here C equals mean old housing divided by mean young housing. Strict old retention gives $0 < C < 1$; the estate condition gives $D < L < \ell$. The other stated private constraints must also be checked.

Convergence. A sufficiently small permanent credit reform has a locally unique converging equilibrium if:

$$\ell + (3 + q)C > 4D. \quad (15)$$

This holds automatically if $w > d$, or if $4D \leq \ell$. Substitution of the household budgets and cohort law into housing clearing gives two roots inside the unit circle precisely under (15), with a third root above one. The initial cohort and its predetermined old assets select a unique local converging path.

Fertility and population. The stationary population response is:

$$\frac{\partial \log N_{hh}^*}{\partial \log d} = J := \frac{Dr}{q\ell(1 + C)} > 0. \quad (16)$$

Initial fertility needs an additional condition. When $q \geq 1/2$ and $r > 1$, a sufficient restriction, again entirely in primitives, is:

$$\ell C[\ell + (1 + q)C] > L(\ell - D + C). \quad (17)$$

There is no equilibrium price or borrowing multiplier in this restriction. The full proof also gives an exact primitive test and an admissible example with lower initial fertility and a larger final population.

The plotted example. Figure 2 uses:

$$\begin{aligned} q &= \phi = 4/5, \quad b = 1/5, \quad y = 19/20, \quad \alpha = \beta = 2/5, \quad \gamma = 3/10, \quad \omega_B = 2, \\ \kappa &= 1/2, \quad \vartheta = 2/15, \quad \nu = 2, \quad h_O^{\max} = 2, \quad h_R^{\max} = 1/4, \quad \bar{H} = 1213/928. \end{aligned}$$

Its baseline has $P = Y = O = 1$ and $(x, h, n) = (95/232, 1, 1/2)$. Both inequalities above are strict. The first-order young-population response is:

$$\left. \frac{\partial Y_t}{\partial d} \right|_{d=1} = J + .87792408 \dots \lambda_1^t - 1.16234288 \dots \lambda_2^t, \quad (18)$$

where $J = 345/1213$ and the stable roots are $\lambda_1 = .05958565 \dots$ and $\lambda_2 = .26160613 \dots$. The original equations define these coefficients exactly. A uniform remainder bound preserves positive population increments for small finite reforms here.

The mixed-model extension uses smooth aggregation and uniformly strict conditional owner and renter choices. It retains the actual pre-reform old distribution and the extra future prices entering tenure choice. The full proof gives an admissible income and wealth distribution around this example.

Appendix C. A population condition in primitives

The stationary comparison can be made explicit even with a positive child goods cost. Retain homogeneous entrants, all owners and $\tau^p = 0$. Assume the purchase limit binds strictly, young saving is positive, and old retention and estate restrictions are slack. This is a conditional result for these household choices.

For this calculation only, define the following quantities from primitives:

$$\ell = 1 - q, \quad d = \frac{b}{1 - \phi}, \quad \rho = 1 + \beta(1 + \gamma + \omega_B), \quad w_\chi = y + b - \frac{\chi}{\nu},$$

$$X = \frac{w_\chi - \ell d}{\rho}, \quad g = \frac{\beta\gamma}{q\ell}.$$

Here X is adult consumption at replacement fertility, calculated directly from the budget. Suppose $X > 0$ and $\nu\vartheta X > \chi$. The fertility condition then gives stationary young and old housing:

$$h^* = \frac{\kappa}{\nu} \frac{\nu(\alpha + \vartheta)X - \chi}{\nu\vartheta X - \chi}, \quad h^{2*} = \frac{gX}{d} h^*, \quad P^* = \frac{d}{h^*}. \quad (19)$$

The original feasibility and saving inequalities must still hold. In particular, strictly binding purchase rationing requires $(\alpha + \vartheta)X > \ell d + \chi/\nu$.

Since $Y^* = \bar{H}/[h^*(1 + gX/d)]$, differentiation yields:

$$\frac{\partial \log Y^*}{\partial d} = \frac{1}{\rho} \left[\frac{gw_\chi}{d(d + gX)} - \frac{\alpha\nu\chi\ell}{(\nu\vartheta X - \chi)[\nu(\alpha + \vartheta)X - \chi]} \right]. \quad (20)$$

Every abbreviation on the right is defined above from primitives. There is no borrowing multiplier or independently determined equilibrium price. Because $\partial d/\partial \phi > 0$, looser credit raises stationary population precisely when the first bracketed term exceeds the second.

The first term captures the decline in old housing relative to young housing. The second captures the extra young housing needed to maintain replacement fertility as goods become scarcer. At $\chi = 0$, the second term disappears and the population sign is positive. At $\chi > 0$, either sign is possible.

For Appendix B's parameters with $\chi = .015$, the derivative in (20) is 0.25659. Young housing is 1.12054 and old housing is 0.34141; purchase rationing remains strict. With $\gamma = .001$ instead, the population derivative is -0.02358 , still with a strictly binding purchase limit. These examples satisfy the original owner problem. They establish the two stationary signs; the second example is not an additional proved transition.

The welfare distinction is concrete. In Appendix B's limiting stationary economy, young housing and fertility stay fixed when d rises, while adult consumption and old housing fall. Differentiating the original owner lifetime value gives:

$$\left. \frac{\partial W^O}{\partial d} \right|_{d=1} = -\frac{1 - q}{x^*} - \frac{\beta\gamma}{d} = -\frac{289}{475} < 0. \quad (21)$$

Thus the demographic prediction and the compensated allocation result answer different questions. A larger stationary population is not itself a welfare improvement.

Verification. The supporting files retain the full proof, scoped independent reviews, symbolic identities, and checks against the original dated household problems. Small finite transitions check the analytical response and initial-old accounting. These computations establish no calibrated policy magnitude or numerical bound for the theorem's neighborhood.
