A Simple Model: Demographics and Timing

A stationary two-period overlapping-generations economy. A potential young household enters with a type

$$i = (y_i, a_i),$$

disposable income y_i and entry wealth a_i inherited from the old who exit as she arrives.

- Young households choose whether to enter the market, then tenure, occupied space, number of children, and saving.
- A young owner carries her house into old age and becomes next period's old incumbent; a young renter reaches old age with no house.
- Old households choose consumption, how much housing to keep, and the estate they leave, then exit.

Entry is a discrete choice against an outside value $\bar{W}^E$ with taste shocks of scale κ_E , so who reaches owner housing is set at entry. Births plus a renewal inflow form the next young cohort, and the exiting estates fund its entry wealth.

Preferences

Children compete with their parents for the same budget and the same house: each child claims χ units of consumption and κ units of space. Over consumption c_i , occupied housing h_i , and number of children n_i , the young household values

$$u_i^Y(c_i, h_i, n_i) = \log(c_i - \chi n_i) + \alpha \log(h_i - \kappa n_i) + \vartheta \log n_i, \quad \alpha, \vartheta > 0.$$

One more child means less space and less consumption left for the adults.

Old households value consumption, retained housing, and a warm-glow estate e_j ,

$$u^O(c_j^O, h_j^O, e_j) = \log c_j^O + \gamma \log h_j^O + \mathcal{B}(e_j),$$

and a young household discounts her own old age by β . Saving carries $a'_i \geq 0$ into old age at gross return $1 + r$; the savings load $k \equiv \beta(1 + \gamma + b)$ is old age's claim on each unit of adult consumption.

Markets and Technology

One fixed stock $\bar{H}$ of divisible floorspace, occupied by renting (R) or owning (O). The segments differ only in the largest size available,

$$\mathcal{H}^R = \{0 < h \leq \bar{h}^R\}, \quad \mathcal{H}^O = \{0 < h \leq \bar{h}^O\}, \quad \bar{h}^R < \bar{h}^O,$$

so family-sized space must be bought, not rented. All space clears in one market, and a no-arbitrage user cost ties the rental rate to the price:

$$q = \rho P, \quad \rho = r + \delta + \tau^P.$$

The renter pays q as rent; the owner pays it as interest, tax, depreciation, and forgone return — equal per-unit value by arbitrage. Selling a house triggers a capital-gains tax that death forgives through basis step-up, a per-unit wedge on housing sold while alive,

$$\bar{\ell} = \tau^g \frac{P \varpi}{1 + \varpi},$$

the only place the model touches inflation.

The Household Problem, Mode by Mode

Conditional on entry, the household picks a tenure mode $m \in \{R, O\}$ and solves

$$W_i^m = \max_{c_i, h_i, n_i, a'_i} u_i^Y(c_i, h_i, n_i) + \beta [\mathbf{1}\{m = R\} V^R(a_{j'}) + \mathbf{1}\{m = O\} V^O(a_{j'}, h_i)]$$

subject to one budget and, for buyers, two financing tests:

$$c_i + qh_i + a'_i = y_i + a_i, \quad \mathbf{1}\{m = O\} (1 - \phi)Ph_i \leq a_i, \quad a'_i \geq 0.$$

Space costs q per unit either way, so tenure bites only through the size limit and the down payment $(1 - \phi)Ph_i$, which wealth in hand must cover. An old incumbent nets $q - \bar{\ell}$ on each unit she sells, valuing kept space *below* market by the tax she avoids; an old renter's demand is wedge-free.

Stationary Competitive Equilibrium

A stationary equilibrium is a user cost q , an asset price $P = q/\rho$, young and old allocations, entry probabilities, and stationary measures such that:

- young households solve their mode problems and choose tenure $o_i = \arg \max\{W_i^R, W_i^O\}$; old households and entry are optimal;
- the single floorspace market clears,

$$H^D(q) = \bar{H};$$

- the old-incumbent measure, the young cohort, and the cohort mass reproduce themselves, and fiscal and housing-income accounts close by lump-sum transfers.

One price equates total demand to the fixed stock. Nothing in that condition asks whether the marginal family-sized unit is held by the household that values it most — that question is the efficiency result below.

All Frictions Collapse Into One Cap

Using $P = q/\rho$, owner housing is bounded by the tighter of the size limit and down-payment capacity:

$$h_i \leq H_i^O(q, \tau^P) = \min \left\{ \bar{h}^O, \frac{a_i \rho}{(1 - \phi)q} \right\}, \quad H_i^R = \bar{h}^R.$$

Renting, the owner size limit, and finance all reduce to one effective family-housing cap. Substituting it into the fertility first-order condition prices the marginal child:

$$\underbrace{\frac{\vartheta (c_i^m - \chi n_i^m)}{n_i^m}}_{\text{willingness to pay for a child}} = \underbrace{\chi + \kappa(q^m + \zeta_i^m)}_{\text{full price of a child}}.$$

A binding cap acts as a per-child tax of $\kappa \zeta_i^m$: children cost more exactly where family-sized space is hard to reach, with market prices unchanged.

The Access Gap

The access gap ζ_i^m is the goods value of one more unit of constrained family space, read off the household's own bundle. For a renter at the size limit,

$$\frac{u_{h,i}^Y}{u_{c,i}^Y} = \frac{\alpha (c_i^R - \chi n_i^R)}{h_i^R - \kappa n_i^R} = q + \zeta_i^R,$$

so she values space above the rent it commands. For an owner the gap separates finance from the size limit,

$$\zeta_i^O = \underbrace{\frac{\mu_i}{\lambda_i^O} (1 - \phi) P}_{\zeta_i^{O,F}, \text{ down-payment margin}} + \underbrace{\frac{\theta_i^O}{\lambda_i^O}}_{\text{size-limit margin}} \geq 0.$$

Either way ζ_i is computable from observed consumption and housing, net of child needs: the young gap from bundles, the old wedge from deeds and the tax schedule.

Where the Cap Binds, Fertility Responds

Under equal scaling at lifetime prices, $\chi = (1 + k)\kappa q^m/\alpha$, the fertility response to relaxing the cap is proportional to the same gap that measures access:

$$\psi_i^m = \frac{\kappa}{\alpha} \frac{\zeta_i^m}{c_i^m - \chi n_i^m} \Omega_i^m, \quad \Omega_i^m = \frac{\frac{\alpha}{h_i^m - \kappa n_i^m} + \frac{q^m}{c_i^m - \chi n_i^m}}{\frac{\vartheta}{(n_i^m)^2} + \frac{\chi^2}{(1 + k)(c_i^m - \chi n_i^m)^2} + \frac{\alpha \kappa^2}{(h_i^m - \kappa n_i^m)^2}} > 0.$$

Holding exposure and pass-through fixed, a larger normalized gap means a larger birth response. The households closest to the cap are the ones whose fertility moves.

Why the Stock Is Misallocated

Move one unit from an old incumbent to a financially constrained young owner:

$$\underbrace{(q^O + \zeta_i^{O,F})}_{\text{buyer's marginal value}} - \underbrace{(q - \bar{\ell})}_{\text{incumbent's marginal value}} = \zeta_i^{O,F} + \frac{\bar{\ell}}{1+r} + \bar{\ell} > 0.$$

The market price cancels. What is left is always positive: the young buyer's financing gap, plus her own anticipated capital-gains tax, plus the incumbent's realized one. The stock clears and is still misallocated — not because the old occupy housing, but because their tax lock-in sits next to young households with unmet access gaps. The tax wedges are transfers, not resources, so the reallocation is a Pareto improvement.

The Quantitative Model

Environment

A household lives 17 four-year periods, ages 18 to 82; it enters at 18 as a renter and dies at 82. Write the child block as (n, s) : n is the number of children and s the child-aging stage.

- **Income:** a five-state persistent process $z \in \{0.6, 0.8, 1.0, 1.2, 1.4\}$, with stationary weights $(0.10, 0.20, 0.40, 0.20, 0.10)$ and Markov persistence 0.85 — and a deterministic age-earnings profile e_j .
- **Children:** up to two children per household. A birth opens one dependent-child stage that exits with hazard $2/9$ each period; when it exits the children leave home and their goods and space costs switch off.
- **Fertility:** completed fertility is chosen once, inside the fertile window ages 18 to 42, subject to taste shocks — one shot, not a sequential birth hazard.
- **Choices:** the household picks **fertility** $\nu \in \{0, 1, 2\}$ while fertile, then **tenure** (rent or own), **size** (a room on the renter or owner menu), and **saving** b' .

So the two-period child cost (χ, κ) becomes a lifecycle of family-size-dependent needs that arrive with a birth and expire when children mature.

Preferences

n : number of children; s : child-aging stage (stochastic); $m(n, s) = n \mathbf{1}\{1 \leq s \leq K_c\}$: children currently at home, $K_c = 1$.

Flow utility. Over residual consumption and residual housing services x :

$$u(c, x; n, s) = \frac{[(c - \bar{c}(n, s))^\alpha x^{1-\alpha}]^{1-\sigma}}{1-\sigma} + \psi_{\text{child}} m(n, s), \quad \sigma = 2.$$

Subsistence requirements. Depend on family size:

$$\bar{c}(n, s) = \bar{c}_0 + \bar{c}_n m(n, s), \quad \bar{h}(n, s) = \bar{h}_0 + \underbrace{\bar{h}_{\text{jump}} \mathbf{1}\{1 \leq s \leq K_c\}}_{\text{first-child housing margin}} + \bar{h}_n m(n, s).$$

Housing services. Renters take x^R capped at 6 rooms; owners get a service premium $\chi_o > 1$:

$$\underbrace{x^R = \max\{h^R - \bar{h}(n, s), \varepsilon\}}_{h^R \leq h_{\max}^R = 6}, \quad \underbrace{x^O = \chi_o \max\{h - \bar{h}(n, s), \varepsilon\}}_{\chi_o > 1}.$$

The additive child term is tied to children at home, so it shuts off once the child state matures.

Bequests

Terminal utility at death, over completed children $N(n, s)$:

$$B(b, h, n, s) = \theta_0 \max\{1 + \theta_n N(n, s), 0\} \frac{(\theta_1 + \tilde{b})^{1-\sigma}}{1-\sigma}, \quad \tilde{b} = \max\{b + \mathbf{1}_{\text{own}} p h, 0\}.$$

- θ_0 governs the overall bequest motive (the saving level).
- θ_n scales the bequest with completed children $N(n, s)$ — the parent–childless saving differential.
- θ_1 is a shift on bequeathable wealth inside the CRRA term.

Bequeathable wealth $\tilde{b}$ uses the *gross* owner housing value $p h$; the transaction-net sale value $(1 - \psi)p h$ enters tenure transitions, not this terminal call.

Housing, Tenure, and Budget Constraints

Household chooses a room on the renter or owner menu: $h^R \leq h_{\max}^R = 6$; $h \in \{2, 4, 6, 8, 10\}$ (owner ladder). Family-sized rooms are reachable only through owning.

Renters ($h = 0$). With rent $r(p) = (q + \delta + \tau_H)p$ and gross return $R = 1 + q$:

$$b' = Rb + y(j, z) - c - r(p)h^R, \quad b' \geq 0, \quad h^R \leq h_{\max}^R.$$

Owners. Depreciation and property tax are flow costs of the occupied rung; borrowing is collateralized:

$$b' = Rb + y(j, z) - c - (\delta + \tau_H)p h, \quad b' \geq -\phi p h, \quad \phi = 0.80.$$

Tenure transitions. Purchases subtract the full $p h'$; sales credit $(1 - \psi)p h$; a purchase is feasible only if wealth in hand clears the down payment:

$$b^+ = \begin{cases} b - p h', & R \rightarrow O(h'), \\ \max\{b + (1 - \psi)p h, 0\}, & O(h) \rightarrow R, \\ b + (1 - \psi)p h - p h', & O(h) \rightarrow O(h'), \end{cases} \quad b + \mathbf{1}_{\text{own}}(1 - \psi)p h \geq (1 - \phi)p h'.$$

- q : gross bond rate; δ : depreciation; τ_H : property tax; ψ : transaction cost; $\phi = 0.80$: financed share.

~~Movers and newly matured children arrive as renters, then choose tenure by argmax.¹~~

¹Tenure is a deterministic arg max; the logit smoothing scale $\kappa_{\tau} \approx 8.3 \times 10^{-7}$ is calibrated to zero.

Births and Equilibrium

Birth choice. While fertile the household draws $\nu \in \{0, 1, 2\}$ from a logit over continuation values, with scale κ_{fert} :

$$\Pr(\nu \mid b, \tau, j, z) = \frac{\exp\{V_{\nu, s_\nu}(b, \tau, j, z)/\kappa_{\text{fert}}\}}{\sum_{\ell=0}^2 \exp\{V_{\ell, s_\ell}(b, \tau, j, z)/\kappa_{\text{fert}}\}}, \quad \text{TFR} = 2 \sum_{\nu=0}^2 \nu \Omega_\nu.$$

The calibrated scale κ_{fert} sits at its *lower* bound: the calibration wants birth choices as sharp as allowed — near-deterministic — and the poorest types' birth probability is exactly zero. TFR doubles the per-household expected births because each fertility draw is one adult's contribution.

Market clearing. One price p equates housing demand to a unit-elastic supply curve:

$$H^s(p) = H_0 \left(\frac{(q + \delta + \tau_H) p}{\bar{r}} \right)^\xi, \quad \xi = 1, \quad H^d(p) = H^s(p).$$

The theory section's fixed stock $\bar{H}$ is the limiting simplification of this ($\xi \rightarrow \infty$); the quantitative model clears against the coded unit-elastic supply.

What Maps to What

Every theory object has a quantitative counterpart — these set up the bridge slides.

simple model	quantitative model
user cost $q = \rho P$	user-cost flow $(\delta + \tau_H)p$ at the single price p
down-payment friction $(1 - \phi)P$	collateral bound $b' \geq -\phi p h'$, $\phi = 0.80$
effective cap $\min\{\bar{h}^O, a_i \rho / ((1 - \phi)q)\}$	owner ladder $\{2, 4, 6, 8, 10\}$ vs. renter cap 6, against the down payment
child costs χ, κ	consumption floor $\bar{c}(n, s)$ and housing floor $\bar{h}(n, s)$
access gap ζ_i	shadow value of the collateral/size constraint on family space
capital-gains wedge $\bar{\ell}$	transaction cost ψ on owner sales
fixed stock $\bar{H}$	unit-elastic supply $H^s(p) = H_0(r(p)/\bar{r})^\xi$, $\xi = 1$

The down payment is the load-bearing bridge: $\zeta_i^{O,F}$ in the theory and the $\phi = 0.80$ collateral bound in the quantitative model. The one place the two differ openly is supply: the theory fixes the stock, the quantitative model clears a unit-elastic supply curve.

Household Policies: The Down Payment Draws a Line

Deterministic argmax policies on common occupied childless-renter states

- Consumption and housing services rise smoothly in liquid wealth, but tenure is a step: renting below a wealth threshold, owning above it.
- The threshold is the down payment. A household buys only once its liquid wealth clears $(1 - \phi)ph'$ on the size it wants, so the owner region opens at higher wealth for larger units.
- These are childless-renter slices, so the fertility panel is flat at zero; the birth margin lives at older ages, shown next.

The collateral bound $b' \geq -\phi ph'$ is not a smooth cost; it is the discrete wealth line at which tenure flips.

Consumption by Tenure: Saving Toward the Down Payment

Consumption policies by tenure

- Conditional on tenure, consumption is smooth and increasing in liquid wealth — the standard CRRA policy within a fixed housing regime.
- The localized dips sit just below the purchase thresholds: households cut consumption to accumulate the next down payment $(1 - \phi)ph'$.
- The flat left segment is the consumption floor at the borrowing limit, where the constraint $b' \geq -\phi ph'$ binds and consumption cannot fall further.

The dips are the down payment felt in the consumption policy: saving to clear the collateral bound, not a smooth intertemporal motive.

The Birth Policy: Late, and by the Better-Off

- Expected births are near zero through the twenties, climb through the thirties, and peak just before the fertile window closes near age 42.
- At every age the birth probability is ordered by income: the $z = 1.4$ households have children at more than twice the rate of the $z = 0.6$ households.
- Births are timed to arrive after wealth and housing access are in place, which is why the purchase and the birth land together at the deadline.

Children are a late, resource-gated choice here: family space must be affordable before the birth is taken

Housing over the Lifecycle: The Rent-to-Own Transition

- Mean housing services trace a hump: households scale up through their thirties and forties as children arrive, then draw down slowly in old age.
- The profile fans out by income. High-income households climb onto the family-sized rungs; the lowest income line stays flat near the rental floor and never makes the jump.
- The rise is the rent-to-own family transition: the mid-life bulge is bought owner space, financed against the collateral bound.

Space and children move together over the lifecycle, and the households that cannot finance the space are the ones held at the floor

The Stationary Distribution: Where the Wealth Sits

Ergodic mass over the occupied liquid-wealth grid

- Renters, 40% of the population, pile up at zero liquid wealth: they hold no housing collateral and save little against the borrowing constraint.
- Owners, the other 60%, spread into negative liquid wealth. Among young owners 83% carry negative liquid balances, having levered up to the down-payment limit to buy.
- The positive tail is old and asset-rich, the households that bought long ago and paid the mortgage down.

The cross-section is exactly the collateral story: constrained renters at zero, leveraged buyers in the red, and the wealth accumulating in post-purchase old age.

Tenure and the Owner Ladder in the Cross-Section

- Ownership crosses renting near age 43: only 23% of the young target ages 25–34 own, against 89% of the old.
- Conditional on owning, most sit on the small rungs: 40% hold 4 rooms and only 57% reach the family-sized 6-plus rooms.
- Owning arrives late and starts small, so young families are the group least likely to hold the space a child requires.

Who owns what size is the equilibrium face of the access gap: the family-sized stock is held by the old, not the fertile.

The Single Housing Market Clears

- The price p is set so that owner-occupied plus rented services equal the fixed stock $\bar{H}$; demand and supply agree to a relative residual of 2×10^{-4} .
- At that price the asset value is $p = 0.67$ and the flow user cost $(\delta + \tau^P)p = 0.19$ per room, the rent every household pays for space.
- Every policy and distribution shown so far is read off this cleared equilibrium, not a partial-equilibrium guess at the price.

The equilibrium is a genuine fixed point: the price that clears the stock is the same price households optimized against.

Calibration

- The fit is a 14-moment SMM table against 13 estimated parameters.
- Empirical inputs: room and ownership moments from the ACS, and lifecycle wealth, tenure, and birth-housing moments from the PSID; entry wealth is the PSID young-childless-renter distribution, carried in rather than estimated.
- Externally fixed: the financed share $\phi = 0.80$ and $\sigma = 2$.
- The rental cap is not estimated. We set $\bar{h}^R = 6$ rooms from an external rule — the 90th percentile of rental unit sizes, following Greaney, Parkhomenko, and Van Nieuwerburgh (2025), measured in our own ACS sample.²

The precise statement is that the p90 of renter sizes falls in the 6-room bin, so the maintained cap is a measured feature of the rental stock, not a free parameter.

²Search at $N_b = 120$ wealth nodes and verify at $N_b = 240$; a coarser grid tunes to numerical noise, so the reported fit is checked at the finer resolution.

The Data Do Not Fight the Cap

Re-solving at nearby cap values traces out a shallow valley around the external rule:

$\bar{h}^R$	best loss	status
5.5	7.69	converged
6.0	6.31	converged
6.5	6.24	still improving
7.0	7.15	preliminary

The data mildly prefer 6.5, but both flanks rise sharply, so the cap is identified and its minimum sits within half a room of the external value. We keep $\bar{h}^R = 6$ as the baseline and carry 6.5 as a robustness check.

Model Fit

moment	target	model	gap	contrib
tfr	1.918	1.947	+0.029	0.02
childless_rate	0.188	0.260	+0.072	0.10
own_rate	0.576	0.531	-0.045	0.20
own_family_gap	0.168	0.298	+0.131	0.77
housing_increment_0to1	0.664	0.617	-0.048	0.03
old parent-childless wealth gap 65–75	1.007	0.835	-0.172	0.06
childless renter mean rooms	3.805	3.656	-0.150	0.13
childless owner share rooms ≥ 6	0.596	0.595	-0.001	0.00
old nonhousing wealth/income median	2.231	2.328	+0.097	0.01
young renter wealth/income	0.179	0.354	+0.175	0.37
owner–renter mean rooms	2.419	2.152	-0.266	0.85
old_age_own_rate	0.764	0.892	+0.128	2.63
own_rate_2534	0.341	0.226	-0.115	1.06
parent 3+ vs 1–2 rooms gap	0.368	0.264	-0.104	0.09

The family-ownership moments fit well. Three misses carry the loss: old-age ownership is too high, young ownership and wealth are mistimed, and childlessness overshoots.

Lifecycle Profiles: A Deadline Purchase

- Ownership jumps at the last fertile age, not gradually before it.
- Births cluster at age 33 with a spike at the deadline; in the data they peak near 27.
- Liquid wealth drops sharply at the family purchase, as households lever up to the limit.

The remaining fit problem is timing: the model buys and gives birth too late.

What the Misses Are Telling Us

diagnosed miss	fix designed, not yet adopted
Old-age ownership is 0.892 against 0.764 in the data.	Give old owners a health, mortality, or downsizing exit.
Young ownership is 0.226 against 0.341, and young wealth is 0.354 against 0.179.	Fix fertility timing, rather than re-searching the same parameter box.
Childlessness by income runs the wrong way.	Add a child time cost, so children cost time as well as goods and rooms.
The misses hang together: late fertility and no old-age exit are doing work that no parameter can do cleanly.	

The Access Gap Shows Up in the Calibration

- Among fertile renters constrained by the rental size limit, $\zeta/q = 1.28$.
- These renters value family space at $2.3\times$ market user cost.
- A share 0.734 of the fertility-response mass sits on households with $\zeta > 0$.
- The share is robust to numerical resolution, to how the targets are weighted, and to the owner ladder.

This is the equal-scaling prediction in the calibrated model: fertility exposure rises with the normalized gap $\zeta_i^m / (c_i^m - \chi n_i^m)$.

Births Trigger the Purchase at the Deadline

- About 29% of the age-42 cohort buys in that single period.
- Seven in ten of these buyers are parents, and half have a newborn.
- Buyers arrive with slack: the average one is about 10 wealth-grid cells above its down-payment threshold.

The purchase margin is a birth-timing margin, not slow saving finally crossing the constraint.

Who Holds the Family-Sized Stock

The concentration of family-sized homes among post-fertile households is a fact in the data — and the model reproduces it, indeed too strongly:

share of rooms ≥ 6 owner stock held by	data	model
households aged 46+	72%	87%
households with no children at home	55%	72%
fertile-age households (30–45)	25%	13%

The households with the largest measured access gap hold the smallest share of the family-sized owner stock. The model overstates the concentration in the two diagnosed directions: births arrive too late, and old owners never exit.³

³Data: ACS/IPUMS household heads, 2012–2023, matched metro sample, head person-weights; 7.1 million owner households with six or more rooms.

A Price Instrument Capitalizes but Barely Moves Births

- Consider a 2% tax on large homes.
- Large-home prices fall by 12.3%.
- Fertility hardly moves: $\Delta \text{TFR} = +0.004$.
- The response is robust to numerical resolution, to the housing menu, and to the weighting of targets.

A pure price instrument capitalizes into house prices; it does not create births.

Birth-Linked Purchase Grants Move Fertility

A grant paid at a birth-linked purchase raises fertility, and the response grows with the size of the grant:

grant size	ΔTFR
0.1	+0.01
0.4	+0.13
0.58	+0.26
1.0	+0.49

Prices barely move — large-home prices rise about 1%.

- One caveat: a small conditional grant can pull purchases back before the birth, delaying them through anticipation.

Grants move the birth margin because they relax the owner financing gap $\zeta_i^{O,F}$.

A Package That Decentralizes the Reallocation

Tax the incumbent stock and spend the revenue on young buyers' access:

$$\text{large-home tax} + \text{birth-linked purchase grant} \Rightarrow \Delta \text{TFR} = +0.15, \quad \Delta p_{\text{large}} = -11\%.$$

The tax lowers what incumbents will pay to keep large units; the grant closes the young side's financing gap at the birth margin. Revenue-funded, it is the decentralized version of the planner's move — and it works through access, not price.

The Bridge, in Three Numbers

1. Access: fertile renters at the cap have $\zeta/q = 1.28$, and 0.734 of the fertility-response mass sits on households with $\zeta > 0$.
2. Allocation: 87% of the family-sized stock is held by post-fertile households.
3. Policy: the tax-funded access transfer raises TFR by 0.15 while cutting large-home prices 11%.

The same object ζ measures fertility exposure and stock misallocation, and the package is the decentralized version of the planner's reallocation.

Where This Version Falls Short

- Several parameters sit at their search bounds.⁴
- The fertility taste-shock scale κ_{fert} is at its *lower* bound: birth choice is near-deterministic and the poorest households' birth probability is exactly zero. This strengthens the reading that the child-price structure, not the taste shocks, drives the misses — and a near-arg max birth choice makes the fertility moments numerically sensitive to small changes in the price of family space.
- Fertility is mistimed: births cluster at 33, against a data peak near 27.
- Planned extension: a child time cost, so children are priced partly in foregone income.
- Planned extensions: an old-age exit margin, and childlessness targets consistent with the estimand.

These belong in the draft as honest limitations, not as settled calibration details.

⁴Eight of the 13 estimated parameters are at or against a bound at the current calibration — evidence that the parameter space is compensating for missing mechanisms, not a failure of the search.

Conclusion
